INDEX TO VOLUME XVI

GENERAL ALPHABETICAL INDEX

Entries from the Synopsis of Periodical Literature are indicated by S. (Synopsis); from the analysis of Current Electrochemical, Chemical and Metallurgical United States Patents by P. (Patents).

A

Abrasive. Artificial. Williams.....	599
Acetone and methyl alcohol. From soda pulp industry. White and Rue.....	182
Acetone. By-product from soda pulp industry. Lawrence.....	416
Acids. Transportation by water. Morris. (S.).....	227
Acid-resisting alloys. Kowalke.....	581
Aetna Explosives Co., oil cracking.....	657
Ainsworth, Wm.....	167
Air drying. Hering.....	187
Air drying. Correction. Hering.....	360
Air Reduction Co.....	164
Alcohol. And acetone from soda pulp industry. White and Rue.....	182
—From calcium carbide.....	366
—From molasses. Osborn.....	438
—Methyl. From soda pulp industry. Lawrence.....	416
—Report of U. S. Industrial Co.....	356
Alkali industry in France.....	327
Allison, S. E.....	457

ALLOYS:

—Acid-resisting. Kowalke.....	581
—Aluminum-calcium. Cooper. (P.).....	707
—Arsenic-antimony.....	449
—Bibliography. Estes.....	273
—Bibliography of. Comment on. Anderson.....	360
—Chromium-copper-nickel. (S.).....	608
—Cohalt. Non-corrosive. Kalmus.....	306
—Die-casting copper alloy.....	55
—Electric furnace for melting. Gillet and Lohr. (P.).....	53
—Manganese with brass and bronze. Goldschmidt. (P.).....	400
—Melting of. (S.).....	530
—Nickel-chrome. Brix. (P.).....	228
—Nickel-chromium analysis. Koepfing. Systematic collection of properties by Bureau of Standards.....	365
—Tool-steel. Furness. (P.).....	164
—Zirconium. Cooper. (P.).....	660
Alumina. Bauxite brick.....	210

ALUMINUM:

—Alloys with calcium. Cooper. (P.).....	707
—Canadian production. Demis.....	628
—From aluminum carbide. Herschman. (P.).....	531
—In France.....	328
—Melting aluminum chips. Gillet and James. (S.).....	52
—Production. Haff. Mailloux.....	496
—Production in 1916.....	268
Aluminum. Soldering compound. Stewart.....	660
Aluminum carbide. Production. Barnet. (P.).....	609
Aluminum carbide. (S.).....	530
Aluminum chloride process of benzene and toluene production.....	486
American Association for the Advancement of Science. Symposium on structure of matter.....	72
—Chemical section.....	75
—Committee urges more publicity on research laboratories.....	179
American Ceramic Society. Annual meeting.....	305
American Chemical Society.....	305
—Kansas City meeting. Announcement.....	405
—Program.....	465
—Editorial on.....	423
—Report.....	481
—New York Section: Celebration of twenty-fifth Anniversary.....	308
—New York Section: Meeting.....	677
American Electrochemical Society.....	633
—Buys Liberty Bonds.....	405
—Detroit meeting: Program.....	545
—Editorial on.....	567
—Report.....	567
—New York Section: Announcement of meeting.....	71

American Electrochemical Society—Continued

—New York Section. Symposium on New York Mining Engineers on smelter smoke and fume problem.....	128
—Niagara Falls Section: Officers.....	335
American Gear Manufacturers' Association. Report of convention.....	640
American Institute of Chemical Engineers.....	55
—New York meeting: Program of.....	81
—New York meeting: Report of.....	149
—Program of Buffalo meeting.....	640
American Institute of Mining Engineers.....	127
—New York Meeting Program.....	248
—Report.....	554
—St. Louis meeting. Zinc plants in district.....	772
—Southeast Missouri mills.....	16
—Chicago Section meeting.....	128
—Colorado Section: Meeting report.....	335
—Columbia Section: Meeting of.....	308
—New York Section: Opportunities for American capital in foreign fields.....	71
—New York Section: Announcement of meeting.....	676
—War problem meeting.....	86
—Utah Section meeting.....	629
American Iron and Steel Institute. Report of annual meeting.....	190
American Mineral Production Co.....	628
American Physical Society. Meeting with A. A. S.....	199
American Society for Testing Materials. Program of annual meeting.....	373
American Smelting and Refining Co. Work on smoke abatement.....	300
Ammonium sulphate. From by-product gas producer. Tarr.....	484

ANALYSIS:

—Babbitt metal and journal bearing linings. Koet.....	85
—Babbitt and white metals. Hagmaier.....	84
—Cadmium in brass.....	604
—Glass.....	259
—Light oils. Egloff.....	319
—Nickel chromium alloys. Koepfing.....	487
—Oxygen in manganese ores.....	124
—Phosphorus in high speed steel.....	548
—Rapid filtering. Schleicher.....	71
—Recovery of chinchonine. From solutions used in tungsten analysis. Hagmaier.....	12
—Recovery of molybdic acid from phosphorus filtrates. Hagmaier.....	588
—Rutile. Hagmaier.....	418
—Training the works chemist. Lathe. Vanadium steel. Kraus.....	263
—Zinc. Hastings.....	483
—Zinc.....	454
Annealing. Furnace. Stevens. (P.).....	444
Antimony. Metallurgy. De Cew.....	533
Antimony. Plating.....	81
Apparatus. Chemical engineering. Miles A. R. G. Mining Co. Mill.....	245
Arc. Chemistry of. Mott.....	581
Arc Welding Machine Co. Welding system.....	108
Armour plate plant for West Virginia.....	534
Arsenic. Recovery from fumes. (P.).....	284
Arsenic-antimony alloys.....	449
Asbestos. Hydraulic press.....	45
Asphalt. Nature and origin. Richardson.....	25
Asphalt. Effect of overheating.....	487
Astor, Vincent. Chamber of Commerce dinner. (Ed.).....	123
Astra lead burning apparatus.....	709
Atom. Structure of.....	592
Automobile. Use of grinding wheel.....	617

B

Babbitt metal. Analysis of. Hagmaier.....	85
Babbitt. Analysis. Koet.....	300
Bacon, E. C.....	617

Bag for filtering fume. Cameron (P.)...	284
Ball mills. Being used by gold mining industry.....	5
—Duroloid pebbles.....	356
—Harding.....	417
—Marcy mill. Marcy.....	344
Bancroft, W. D.....	232
Banks, John H.....	405
Barium. Use of barium compounds in desugaring.....	439
Barnard, E. A.....	350
Barstow Management Association.....	296
Bauxite brick.....	210
Bauxite. Shipments from British Columbia.....	624
Bayle, E. J.....	405
Baylis, J. R.....	166
Beckers, Wm.....	36
Beckman, J. W.....	113
Beet molasses. Osborn.....	437
Beets: Sugar from. Benjamin (P.).....	286
Bel, Alexander Graham. Poem on.....	628

BENZENE (Benzol):

—From petroleum. Egloff.....	492
—From coal gas. Corrections to Sperr's paper.....	301
—Recovery from coal gas. Lessing (S.).....	283
—Recovery from gas. Sperr.....	135
—Rittman oil cracking process. Bender (S.).....	657
Berry, George M.....	166
Bethlehem Steel Co., Potash from Blast Furnace.....	205
Birkeland-Eyde nitrogen fixation furnace. Doyle (P.).....	53
Bismuth. Basic salts. Mutscheller.....	594
Bismuth. Exposure.....	486
Black Metal Reduction Co.....	419
Bluestone: Manufacture of. Addicks.....	689
Bogert, M. T.....	711
Boiler Plate. Sodium hydroxide action. Merica.....	497
Boiler settings. Brick used.....	214
Bolivia. Our trade with.....	623

BOOK REVIEWS:

—Anon: Selling your services.....	233
—Jacon and Haimor. The American Petroleum Industry.....	348
—Bond. The Engineer in War.....	167
—Burdick. Chemical Tests for Minerals.....	457
—de Vivaldi-Coaracy: Elementos de Electroquímica.....	167
—Edwards: The Physico-Chemical Properties of Steel.....	167
—Fay: Microscopic examination of steel.....	537
—Handbook of Chemistry and Physics.....	350
—Hansen and Coburn. Diseases of Occupation and Vocational Hygiene.....	167
—Hurley. Awakening of business.....	537
—Johnson. Blast furnace construction in America.....	663
—Lovelace: Annual Chemical Directory of the United States.....	664
—McWane: Pipe and Cast Iron Ware fare.....	233
—Martin and Dancaester. Text Book of Inorganic Chemistry. VIII. The Halogens.....	233
—Mineral Industry 1915. Edited by G. A. Roush.....	233
—Moses and Parsons. Elements of Mineralogy and Petrology.....	457
—Blowpipe Analysis.....	664
—Payne: Founder's Manual.....	233
—Report on the Fertilizer Industry. Federal Trade Commission.....	664
—Russell. Operation of Gas Works.....	711
—Scott. Standard Methods of Chemical Analysis.....	537
—Venable. Radio-activity.....	378
Boulder Tungsten Products Co.....	362
Bramson, C.....	406
Brass: Alloying with manganese. Goldschmidt and Weil (P.).....	400
—Grain size determination on works.....	378
—Influence of arsenic. Smalley (S.).....	607
—Melting. Thornton (S.).....	529

Brazing material. Fuller (P.)	400
Brick: Bauxite	210
—Chromite	210
—Fire clay	210
—Magnesia	209
—Silica. New uses. Gray	209
Brines. Examination	485
Bristol. Automatic temperature controllers	347
Bronze: Alloying with manganese. Goldschmidt and Weil (P.)	400
—Tests on Ampco bronze	510
Brown, E. M.	536
Brown, David H.	415, 423
Budovak and Budovak apparatus	154
Buffalo Mines, Ltd. Annual report	72
Bureau of Standards. Properties of metals and alloys. Study of	365
—Opening of Washington station	165
—Station at Golden, Col.	664
—Work of	111
Bureau of Standards. Properties of metals and alloys. Study of	365
Burrell, Geo. A.	56, 617

C

Cadmium. Metallurgy of. Jurczka-Ralston	146
Calcium. Alloys with aluminum. Cooper (P.)	707
Calcium carbide: Alcohol from	366
Calcium carbide: In France	325
Calcium carbide furnace with by-product recovery	706
Calcium fluoride. Used in potash process	702
California oil fields	454
California. Survey of resources	661
California Trona Company. Case of the Government against	15
Cambridge Glass Co.	296
Campbell, J. A.	457
Canada: Potash from feldspar. Benham (S.)	704
Canadian Pacific Railway. Hydro-electric exhibit	455
Candle industry: Twitchell process. Itiner	144
Carbides. Researches on. Briner (S.)	530
Carbon articles. Manufacture of. Clymer (P.)	659
Carolina, Clinchfield & Ohio R. R. New plants along	364
Carpenter, J.	350
Carrier, C. F., Jr.	406
Carty, J. J.	457
Case-hardening of steel. Stenger	425
Castings. Preparation of iron for Krantz (P.)	107
Cautic alkali manufacture. Ascherof (P.)	107
Cautic soda industry in France	327
Celite. Progress in use of	54
Cells. Use of standard cells. Koerner	45
Celluloid in Japan	456
Cellulose: Electrical treatment. Nodon (P.)	107
Cement Mills. Potash from	657
Cement: Potash from, Riverside plant	701
Cementation of iron and steel. Thum	385
Cementation of steel. Stenger	425
Cements: Plie. Barnett	321
Census of New York City's factories and mercantile houses	632
Census of technical men	422
Centrifugal pump on colloids. Ayres	700
Centrifugal pump. De Lavay	660
Chemical engineering equipment. Development in. Miles	154
Chemical engineer. Training of	421
Chemical industries. Canada. Illustrations	487
—Human side of development. Thompson	149
—Japan. Nishida	505
—Switzerland. Potash from	415
Chemical market. Review of 1916	37
Chemical porcelain. Binus	395
Chemicals: Demand in Spain	239
Chemist. The call for. Moody	641
Chemist. Training the works. Lane	103
Chemists' Club. Annual meeting	566
Chemists' Club Employment Bureau	641
Chewing gum. Chemistry of	486
Chile: Field for capital	478
—Nitrate industry. Hobbs	525
China. Production of salt in Szechuen province	32
Chincholine. Recovery of. Hagaman	70
Chlorine compounds: French manufacture	425
Chlorination. Photochemistry of. Taylor	76
Chrome brick	210
Chromium-copper-nickel alloy (S.)	608
Cincinnati: University of. Dedication of chemical laboratory	4, 1
Cincinnati: University of. New chemistry building	367
Cleaver, C. H.	665
Cline waterpower bill	173
Coal. Action of solvents on. (S.)	282
—Powdered	614
—Recovery of benzol from coal gas. Lessing. (S.)	284
Coal-gas for metal melting. (S.)	530
Cobalt. Addition to very pure commercial iron. Kalmus and Blake	8
Cobalt. Non-corrosive alloy. Kalmus (S.)	706

COKE

—Bee-hive production in 1916	718
—By-product. (Ed.)	68
—Following in low-temperature coking	247
—Increasing use as boiler fuel in England. Note	158
—Necessity for by-product ovens	175
—Recent developments in by-product industry in Japan. Kurahashi	700
—Recovery of benzol from gas. Sperr	135
Coke Ovens. By-product construction	216
—Briek use in beehive ovens	214
—Waste heat from beehive oven industry. Pratt	27
Colloids. Effect of centrifugal force. Ayres	190
—Technological aspect	474
Colorado Scientific Society. 326th meeting	16
Columbia University. Course in laboratory organization	609
Colville. Archibald	167
Concentration. New mills	245
—Colorado tungsten ores. Fischer	559
—Elsol dry concentrator	709
—Graphite, gunpowder, and malt. Wiard	654
—Magnetic separators	632
Condensate cellulose	109
Conder, R. E.	665
Conductivity measurements. Graham	76
Conductors for electric furnaces. Lindstrom	683
Cooling tower for condensing water	710

COPPER:

—Corrosion of tinned copper. Merica (S.)	657
—Exports by countries in 1915 and 1916	544
—Flotation practice in 1916	2
—From mine water	246
—Hydrometallurgical extraction. Weidemann (P.)	227
—Metallurgy of. Schwarz	52
—Operations at Chile. Exploration Co. Rose (S.)	162
—Prospective increase of refining facilities	246
—Refining. Current density. Addicks	311
—Refining. Current efficiency. Addicks	23
—Refining. Impurities in electrolytic refining. Addicks	687
—Impurities in electrolytic refining. Addicks	674
—Refining. Method of connecting electrodes. Whitehead. (P.)	227
—Review of 1916	3
Vaporization of in wirebar furnaces. Butts	85
Wet extraction process. Bradley (P.)	164
Copper sulphate. Manufacture of. Addicks	689
Copper carbide	530
Corporate versus individual effort. Finlay	301
Corrosion of cast iron. Richardson	582
Corrosion. Tinned sheet copper. Merica	657
Cottonseed products industry	624
Cotton. Fumigating	346
Cottrell electrical dust precipitator. Collecting cement dust	702
Cottrell process in practice. Bradley	337
Cottrell precipitation process. Theory. Strong	648
Cottrell, F. G.	648
Couch, James A.	113
Coulter, V. A.	665
Council of National Defense. Personnel of Committees and sub-committees	232
Counter-current decantation. Eames	633
Craver, H. W.	457
Credits. Chemical. Hendrick	126
Crit-point instrument	406
Crook, W. J.	85
Crusher, largest gyratory	286
Cupolas. Brick construction	215
Cuprous oxide photochemical cell	587
Current density in copper refining. Addicks	311
Current efficiency in copper refining. Addicks	23
Cushman, Alerton S.	711
Cyanide. In gold and silver metallurgy	5
Cyanides. Fuerstlering and Philipp. (P.)	315
Cyanides. Nitrogen fixation. Bucher	315

D

Davis, Meyer	56
Decantation. Countercurrent. Eames	94
Degeckirk tungsten mill	565
De Laval centrifugal pump	660
Dessus sugar refinery	40
Detarring gas. Steere	695
Distillers' experiments	488
Dulberg, S. H.	113
Dorr, I. V. N.	132
Dorr metallurgical apparatus	113
Dreyfus, H. H.	288
Dreyfus, G.	166
Duckworth, G.	665
Drucker, A. E.	665
Dryer. Atmospheric drum	223
Drying. Air correction. Hering	360
Drying by air. Hering	187
Dumas, W.	665
Dunkle, W. E.	356
du Pont de Nemours & Co. Annual report	356

Duroloid pebbles	356
Dust collector. Robertson	662
Dutton, F. B.	288
Dwight-Lloyd sintering machine. Improvements. Gayley. (P.)	238

DYESTUFFS:

—Annual meeting of Bradford Dyers' Association	464
—Appropriation	186
—Big companies	471
—Consolidation of large companies	471
—Cooling condensing water	710
—Difficulties of British industry. Whitaker (S.)	282
—Discussion at Textile Club	384
—Japanese by-product coke and dyestuff industry	700
—Organic processes. Ney and Marle	217
—Production in U. S. in 1916	672
—Progress in the American industry. Heber	474
—Society of Dyers and Colorists Meeting. (S.)	607

E

Economics. Our economic future	675
Efficiency. Mental	466
Efficiency engineers. Poem	180
Eilers, Anton	467
Elbridge, D. F.	288
Electric drive in sugar mills	433
Electric porcelain. Barringer	433
Electrochemical industries and the Pacific Coast. Beckman	360
Electrochemical industries. Niagara Falls in 1916	7

ELECTROCHEMISTRY:

—Electrochemical analogies of photochemistry. Mott. (S.)	226
—Exhibit of Canadian Pacific Railway	455
—France. Mailoux	324
—University of Cincinnati. Daum and Davison	367
—In France. Mailoux	265
Electrocyano process	456
Electrodes. Magnetite. Thompson	605
Electrodes. Method of connecting in electrolytic refining. Whitehead. (P.)	227
Electrolytic equivalents of gases. Hering	383
Electrometallurgy in 1916	9
Electron. Enlarged. Hering	598
Electroplating. Causes brittleness in steel springs. Thompson	83
Electroplating. Papers on. (Abstracts) Electrotyping wall coverings. McIndoe. (P.)	587
Elements. Evolution of. Harkins	285
Elevators. Portable	73
Elliot Cresson Medal for E. F. Northrup	534
Elsol dry concentrator	709
Elwood, W. F.	535
Employers' responsibility. Beckman	550
Endosmosis	337
English. Engineers lack of	243
Epicassit for rust proofing	403
Equivalents of gases. Electrolytic. Hering	383
Evolution. Mostrius	358
Exfoliation in case-hardening of steel. Stenger	425
Explosives. Application of nitro-aromatics. Mardick	303
—By-products from manufacture	672
—Comment on nitro-aromatic article. Munroe	360
—Use of nitro-starch. Sadtler	361
Exports. Our export trade	242
Exports. To Hongkong	544
Exposition. Springfield	451
Exposition of Chemical Industries. Third National	670
Extraction apparatus. Automatic. Ogden. (P.)	402
Eyde, Sam	56

F

Fairlie, A. M.	166
Faraday Society. Eighty-first meeting	247
Faraday Society. Symposium on training the chemical engineer	420
Faraday Society. Symposium on osmotic pressure	680
Faraday Society. Symposium on enlarged electron. Hering	350
Farrish, F. G.	350
Federal Dyestuff & Chemical Co. Photo	364
Federal Dyestuff & Chemical Co.	474
Feldspar. Grading of. Wiard	449
Feldspar. Potash from. Blum (P.)	453
Feldspar. Potash from, in Canada. Benham. (S.)	704
Fellowships. University of Utah	536
Fellowships in metallurgy at University of Washington	708
Ferro-alloys. French production	334
—Manufacture of decafluorobenzene	307
—Manufacture of. Ladoff. (P.)	702
—New company in Denver	15

Nineteen Hundred and Seventeen

The enormous prosperity which the chemical and metallurgical industries have enjoyed during the past year, cannot last unimpaired forever; it has been an integral part of the general industrial prosperity of this country and closely related to the international trade conditions brought about by the European war. When the war stops, there will come in this country, too, a period of industrial readjustments. Are the chemical and metallurgical industries as living organisms prepared for this radical change that must come some day? While in an economic as in a gastronomic sense it is bad to have "too much of a good thing," it can be said that in spite of their prosperity the chemical and metallurgical industries in the vast majority are in a thoroughly sound condition, that is in all essentials. As the many reviews of different industries throughout this issue will show, much has been accomplished in enlarging old and creating new establishments and industries. It cannot be expected that all of these will last. But in the larger new undertakings, at least, foresight into the conditions after the war has not been absent. What is needed now more than anything else is a sane, sensible legislative policy in Washington. There are some very discouraging signs—the pork barrel business, the coward stupidity with which the Niagara power problem is being handled, the attempt of penalizing publications of nation-wide importance for the benefit of local papers by new second-class matter rates. But there are hopeful signs, too; most shining perhaps the Tariff Commission soon to be appointed. And we may hope that, as so often before, the common sense and fairness of the American people will win out in spite of the politicians and find the right solution.

"So Nice and Poor"

She lives in a house in New York that is as big as a church and the annual tuition paid for her as a day scholar at school is a sum on which many a self-respecting family has been brought up.

She wanted to spend Sunday in the country with the Shorts. Now the Shorts are people of quality and merit, but not of circumstance. "Are you so fond of Hilda?" asked her father. "Oh," replied the daughter, with that integrity of youth which we have forgotten, "I like her well enough." "That is not convincing," he continued, "why do you want to go?" "Because the Shorts are so nice and poor," answered the girl.

There we have it. They are nice and poor. There are no butlers and second men, there is no governess or anything to disturb the spirit or hinder the flow of soul. The house is honest in its business of providing shelter and food for a family without a lot of uninter-

ested strangers about, earning their living by standing in everybody's way. A house where we can enter the kitchen and talk to the cook; where we can see what is going on. Jealousy and hatred and bickerings are things one can smell if he is young enough, and these things befoul the air of nearly every very big house. In a little one among those that are nice and poor there is no room for such things. A reasonable person, unspoiled by years and conventions, holds to the pursuit of happiness as is duly set forth in the Declaration of Independence. Some of us have forgotten it, and we take occasion, now that Christmas tide and New Year's Day are at hand, to preach a little sermon on the subject.

Few of us have the equipment of heart to fill a large house. We can fill it with vanity and fill it with show. The first is a gift that most of us can find by an inward glance, and the second is easily purchased. We can fill it with rules and with obedience, if we hold to the letter, but it is very hard to fill it with ourselves and have it a pleasant abode withal.

Most of us that are old enough can remember a house or so that was joyous that seemed big and was full of a great big man who was its master, but now-aways, if we look over those that are left, they seem surprisingly small. The modern big house is a palace, built in imitation of establishments designed for kings and queens, and these are next to impossible to fill with the spirit of good-fellowship.

We wish health and prosperity to all our readers. And then we wish them something more, something better and more valuable: that with prosperity may come such growth of understanding and sympathy as makes for the general welfare. There are side chains of antibodies that accompany every experience of life, and one of these is the very devil of vapid pomp, that jumps upon our backs as soon as the money comes rolling in. It spoils us and makes us little in the measure that we think ourselves big. We wish our readers deliverance of this evil and, in all prosperity, that quality of spirit which renders them "nice and poor."

Flotation Practice in 1916

The full effect of the application of flotation to various milling problems in North America has been felt during the past year. The call for increased production of all the metals was answered in some cases by installing flotation plants. In fact, we doubt very much if metal prices could have been held down as low as they have been if it had not been for the use of flotation in concentrating certain ores.

Practically every large copper company which is milling ores is now using flotation and thereby gaining simplicity and compactness in the mill flow sheets and also increasing the extractions over what was formerly possible. The simplifying and condensing of the mills has allowed greater capacities in the same floor space. By merely increasing grinding capacity through the switch from pebbles to iron balls, many companies are now producing almost twice the amount of copper formerly

concentrated, and often at a considerably lower unit cost.

One interesting point which has come up has been the actual testing out of large and efficiently operated mills where flotation was used as the major process. The Minerals Separation Company in years past has tried to get its clients to use flotation for the concentration of the ore with as little auxiliary concentrating apparatus as possible. They have claimed that the greater simplicity of operation gained by reducing the ore directly to the size necessary for flotation is worth the trouble. Of course, ores with more than one mineral, like zinc-lead ores, are exempt from this dictum. Minerals Separation was naturally interested in seeing as large a tonnage of ore treated by flotation as possible and other engineers have wanted to know whether this was the right flow sheet or not. The operation of the big new concentrator at Inspiration has done much toward answering this question, although there is still some doubt about just what it does mean. At Inspiration they find that they still have to operate tables on the flotation tailing, making 10 per cent of their total extraction by this method. Of course, the grinding leaves a considerable proportion of sands and there is also some "oxide" copper caught on the tables which would otherwise escape. As soon as the leaching of the flotation tailing is in operation, the total recovery on the tables could easily be much less. Tables do not cost much to operate and it is a question whether slightly finer grinding would cost more than the operation of these tables. So the Minerals Separation engineers were very nearly right and it may be that they will yet be fully justified. These considerations apply more nearly to large mills like the one at Inspiration than to smaller ones such as that of the Engels Copper Co., in California, where flotation is the only concentration process used.

It was thought for a time that flotation would be a serious competitor to cyanidation, when applied to gold and silver ores, but the general consensus of opinion now seems to be that it will be applied only to ores that are difficult to cyanide and that usually it proves to be a most useful adjunct to cyanidation. If the ore deposit being treated happens to be near a smelter, it is probable that the flotation concentrates will be smelted rather than reduced to bullion by the cyanide process. Otherwise flotation will be used on difficult ores to reduce the ore to a concentrated form, so that very careful cyanidation of a small bulk by highly specialized methods, such as that used in the "high grade" mills at Cobalt, may be practised. The advantages of shipping bullion from distant districts are such that cyanidation will probably not be abandoned unless methods of melting down flotation concentrate, such as those used for cyanide precipitate, can be invented.

With the ability to handle slimes, a return to machinery giving a maximum grinding effect for a given amount of power is being made. Only on ores that are incapable of flotation is the production of slimes still a curse. Crushing of ores for magnetic or electrostatic concentration must still take place in machinery that makes a minimum of slimes, and in tungsten concen-

tration the production of slimes and dust is also usually to be avoided, although one party claims to be able to float scheelite. It is probable that flotation methods will finally be developed to supplant such processes and on that account we look for magnetic concentration and electrostatic separation to be placed in more restricted fields than ever. In fact, with the zinc-iron mixtures, it is probable that the "magnetic" roast will be slightly prolonged to insure alteration of the pyrite, and that the material will then be ground and treated by flotation. This allows of higher extractions of the zinc and of the treatment of more disseminated ores. We are surprised that the companies treating the more complex sulphides in the Western mining states have not adopted this method of separation. For some time there has been known to be available the Horwood process which gives the finely ground ore a flash roast enough to alter the surfaces of the pyrite particles while sphalerite is unaltered, but the roasting of fairly coarsely ground ore, to alter the pyrite deeply enough to allow fine grinding in water just before flotation, removes the objections that were raised to Horwood's process, which required a dry but finely ground feed to the roasters, a thing usually difficult to obtain. Further, as far as we know, it is not a patented process.

Grinding machinery is not the only mill machinery to be altered. Flotation machinery itself has seen a remarkable development during the year and the announcement of the Inspiration machine, the Cole-Bergman, the Kraut & Kohlberg, the Jones-Belmont, the Parral, etc., have appeared and a new type of Janney machine with "air baskets" in the spitzkasten has also made its appearance. Some of these machines have not been designed merely to avoid payment of patent royalties, as some of them quite frankly are, but there is a real advance in the art and some of the mechanical improvements are quite ingenious. The saving in power which some of them allow is considerable and the limit has not been reached. The question of saving power is now quite commonly considered, and it is recognized that where the flotation oils can be added to the ball mills before the pulp reaches flotation, the oil is not only well distributed but increased extractions are sometime possible. Where the oils are added ahead of the ball mills there is very little "agitation" of the pulp necessary during flotation and pneumatic cells of one design or another are probably the logical machines to use under these conditions. Would that patent litigation could cease and the real truth about the benefits of different systems of flotation be made available!

The year has seen the installation of several "sulphidizing" and flotation plants for the treatment of oxidized ores of base metals. At the time of writing oxidized copper is being floated by means of hydrogen sulphide sulphidizing at the Magma mill in Arizona, while lead carbonate ore is being floated by the use of sodium sulphide as a sulphidizer at the Prince Consolidated mill in Nevada. A number of other companies have experimental mills under way. The importance of the treatment of oxidized ores is almost impossible to estimate. The use of small units on such ores will al-

low of the treatment of the oxidized ores on the outcrops of many properties through Nevada, Utah, Arizona, New Mexico, Colorado, Idaho, Montana, Washington, Oregon and California. In these states are thousands of prospects whose outcrop ores are often too low-grade to ship. Flotation of the oxidized ores will allow of their being developed at a profit and besides a flotation mill will treat the sulphide ore which is reached with depth. The further development of processes to treat these ores is hence anxiously awaited.

The flotation process has come to stay. Already it is being used in the treatment of well nigh 150,000 tons of ore daily in North America, and there is believed to be enough new work on foot so that the tonnage will be doubled in about five years.

At the beginning of 1916 the situation in obtaining a supply of flotation oils was somewhat acute. While it is still hard to get all the oils wanted, many of the mills have now found supplies of material with which they can operate, although the most desired materials are sometimes hard to get. Coal tar and creosote from practically all of the intermountain gas plants has been contracted for and much material from the Middle West is now being used. Sage brush oil has been found to be an excellent flotation oil, and a movement is now on foot to distill sage oil from some of the larger "forests" of Idaho, Utah and Nevada.

The Year 1916 in Copper

The year 1916 was one of unprecedented prosperity for the copper producers. The price of the metal increased from 18 cents per pound at the close of the previous year to 33 cents at the close of the past year. So great is the demand for copper that it is estimated that nearly all of the production for the first half of 1917 has been sold at prices around 30 cents per pound.

It seems likely that this condition will continue for the duration of the war in Europe. The end of hostilities will probably cause a decided diminution in the demand for copper; at least until such time as a readjustment can be effected and the reconstruction period is actively under way. Although the shipments of copper from this country to Europe have been larger than ever before, England and France have both been forced to cut heavily into accumulated stocks.

Stimulated by the extremely high prices the copper companies have made every effort to increase their output, and have in most cases succeeded in adding anywhere from 30 to 50 per cent to their production. The Anaconda Copper Mining Company produced about 340,000,000 lb. in 1916 as compared with 235,000,000 in 1915. The Utah Copper Company produced about 225,000,000 lb. in 1916 as against 148,000,000 in 1915. Similar increases have been made by Chino, Ray Consolidated, Granby, and others.

Inspiration has been brought into the producing stage to such good effect that its average production per month for the year was in excess of 10,000,000 lb., and at the close of the year it was producing about 11,500,000 lb. per month. This company has probably

the most modern and up-to-date mining and milling plant in existence. The automatic hoist is a source of wonder to everyone who has seen it. It is astonishing with what smoothness and ease the enormous output of 18,000 tons per day is raised by this equipment. The Inspiration concentrator was the first large copper plant to be put entirely on a flotation basis, and it has been an unqualified success. While tables are in use they merely serve to catch the few coarse grains of mineral which may have dropped back in the flotation machines. Large drag-belt classifiers are used between the flotation machines and the tables for the purpose of desliming the feed to the tables. Experiments, however, have demonstrated that these classifiers are hardly needed, as the work which the tables are called upon to perform would be done equally well without them. It seems to be generally conceded that the scheme adopted by Inspiration of following the flotation machines with tables instead of preceding them is the better practice where the ores undergoing treatment contain the copper minerals in a finely disseminated form and where the concentration ratio is large. The flotation machines catch the fine mineral equally as well in the presence or absence of coarser mineral, and in view of the fact that they operate on a denser pulp than the tables, the arrangement adopted at Inspiration eliminates a lot of dewatering apparatus which would otherwise be needed.

At Anaconda conditions are widely different; here there is an ore containing about four parts of iron for every one part of copper, with the result that the concentration ratio is only three into one. Moreover, the mineral is so coarse that over two-thirds of it can readily be removed after grinding to 2 mm. The coarser table concentrates are so much easier to handle in the smelter and the dust losses are so much less that it would be obviously unwise to grind everything to flotation size before commencing concentration.

The remodeling at Anaconda was completed during the year, and the entire reduction works are now operating on the new basis. The plant has produced in excess of 27,000,000 lb. of copper per month for several months. The normal monthly output is between 25,000,000 and 26,000,000 lb.

The coal-dust fired reverberatories and the 20-ft. Great Falls converters have proved an unqualified success, although from last accounts it appears that the prestige of the latter is likely to be somewhat diminished by the new Smith-Pierce converter at El Paso, which is of exceptionally large size and improved design.

The No. 2 roaster plant, which contains twenty-eight 25-ft. Anaconda-Wedge furnaces, has proved a complete success, and the furnaces are roasting concentrates containing 33 per cent sulphur down to 7 per cent at the rate of 150 tons per day each.

A problem of continually increasing importance to the copper and lead smelter is the prevention of damage to the surrounding country by means of dust and sulphur dioxide. Very little has been done with regard

to the latter except so far as this can be accomplished by dilution of the gases. The precipitation of dust is being effected in several places by means of the Cottrell treater, which under favorable conditions is capable of producing excellent results. At the new smelter of the International Smelting Company at Miami, which treats the concentrates from both the Inspiration and Miami concentrators, Cottrell treaters are used at both roaster and converter plants. At the former the treaters are mounted directly over the furnaces and no dust chamber is used. The installation has been very successful, and the perfection with which the entire smelting plant does its work may be judged from the fact that its recovery is in excess of 97.5 per cent of the copper contents of the concentrates.

The advent of the Chile Copper Company among the ranks of copper producers during the past year has been an event of exceptional importance, partly on account of the huge size of the ore deposits, which will probably eventually result in the enlargement of the reduction plant to a size hitherto unapproached, and partly on account of the fact that this is the first large copper property to depend exclusively upon an electrolytic leaching process. While difficulties have been encountered in starting this plant, nevertheless the production of copper during the past year has been fairly satisfactory and the outlook for the future is very good indeed. The process has been demonstrated successful and the difficulties which remain to be overcome are mostly mechanical.

Work has been pushed as rapidly as possible on the leaching plant of the New Cornelia Copper Company at Ajo and is nearing completion. It is expected that the plant will be making copper in February. The process used has been fully described by Dr. Morse and Mr. Tobelmann in the Transactions of the American Institute of Mining Engineers, and is along the same general lines as that used by the Chile Copper Company. There is, however, no chlorine in the ore, and very little in the water, so that it is unnecessary to use the dechloridizing drums, which are so essential a part of the plant at Chuquicamata. It is the intention to use sulphur dioxide for controlling the ferric iron in the solutions at Ajo.

During the past year a rather unusual condition has developed in that the production of blister copper threatened to overtax the refining capacity of the country. This was foreseen, of course, and large additions were made to most of the refining plants. A new refinery was constructed by the A. C. M. Co. at Great Falls capable of a monthly output of 15,000,000 lb. This plant is up to date in every respect, and makes use of a current density rather larger than is customary in the East, viz., 22 amp. per square foot.

Owing to the low-priced hydroelectric power available, calculations showed this to be the most economical current density at which to operate when all things, including fixed charges on the investment, were taken into consideration. This plant has been operating steadily since last March.

Gold and Silver Metallurgy in 1916

The gold metallurgist has given but divided attention to metallurgical progress during the year. He has been actively occupied with the problems arising from the upward trend in cost of the supplies required for producing his finished material, which, almost alone among commodities, has not appreciated in value. Prosperity has passed him by. He is the mourner at the feast.

Such unsettled market conditions, though responsible for many present inconveniences, hold some promise for the future, through the development of American sources of supply. Thus cyanide of American manufacture has entirely replaced the German product, and it may be said that in quality and uniformity it is equal to the best heretofore imported. Potassium cyanide has quite disappeared from the market, without ill effect on the output of American mines. Incidentally, we note with satisfaction that the manufacturers have ceased to refer their analyses to the potassium cyanide standard, and are quoting the content of sodium cyanide—certainly the only rational classification. If operators will follow this example and finally discontinue reference to "128 per cent cyanide" and kindred absurdities, the cause of precision, at least, will have benefited.

Silesian zinc-dust, formerly the best material available, has been unobtainable since the early months of the war, so that operators have now two years' experience with the American dust. This, at first greatly inferior, has been improved until from at least one source is obtained a dust even superior to the best Silesian grade. The advance in price has stimulated investigations directed to the improvement of precipitation methods and of precipitants, and it is probable that interesting developments in this branch of cyanidation may be expected within the current year. In this connection the recently reported preparation of electrolytic zinc dust is of interest.

Another step in conservation, due to the impelling force of rising prices, may be noted in recent practice at the Homestake, where certain classes of precipitate are retorted for the recovery of the quicksilver content, prior to smelting for gold and silver.

The silver metallurgist passed, in the meanwhile, through much the same experiences. At the nadir of his fortunes a year ago, he has been relieved during the past eight months by a strong market for his metal, so that for him the burden of war prices has been lightened.

The Cobalt district witnessed tremendous appreciation in the cost of aluminium dust and of sodium hydrate, both of which are largely used in the processes more or less peculiar to that district. Perhaps the most striking feature of recent work there is the increasing attention being given to the salvage of minor metals in the ore.

Steady progress has been recorded in the application of flotation to the metallurgy of gold and silver. At Goldfield and in the San Juan plants are in successful operation; at Cripple Creek and Cobalt the process is

receiving attention as a means for the beneficiation of difficult ores. A consideration of the ores under treatment in these districts—copper-bearing sulphides, mixed sulphides of lead, zinc and iron, tellurides and arsenides—indicates clearly the field best suited for its application. It is our impression that the year has done much to establish the practical limitations to its usefulness.

Ores relatively amenable to cyanidation, not requiring roasting or other preparatory treatments and containing no metals of secondary but commercial value, offer little opportunity for flotation to displace established methods. When in such circumstances the newer process is favored, it may be presumed that because of small ore reserves or limited capital unusual stress has been placed on the smaller initial cost of plant. This, one of the strong claims of flotation to consideration, is offset by the fact that it is not a complete process, but must depend on smelting or other subsequent treatment for the final recovery of its metals in marketable form. In the development of the flotation process the equipment of the cyanide operator has been drawn on freely, and several devices, notably Door and Oliver machines, have become standard equipment in the flotation mill.

New mill construction indicates that the gold-mining industry has generally accepted the crushing methods of modern copper mills. The Alaska-Gastineau has scored a sound technical success in its milling operations, however its position marketwise has been affected by the disappointing developments in the mine.

The first successful application of the ball-mill to gold ores was made, we believe, at the Vipond. Now we hear that these mills are to be installed at the Dome, displacing stamps of comparatively recent design. This advance seems reasonable, and we look for its continuance. Too much stress has always been placed on the supposed simplicity of the stamp. The past generation of engineers often spoke of "muscular metallurgy." The phrase was probably coined by a stamp-mill operator. As an amalgamating device, the stamp is pre-eminent, but complete recovery by this means is seldom attempted in these days, and it is probably sufficient thus to care for the coarser particles of gold.

It is to be regretted that published data of ball-mill performance have generally failed to take account of the accessory crushing machines which must both precede and follow it in the flow-sheet if it is to duplicate the product of the stamp. Among these data of crushing, the recent paper by Blickensderfer, in which a test of the Marathon mill is described, is of more than passing interest. This mill is a competitor of the ball-mill, but carries a charge of steel rods instead of balls. The fact that the marathon mill was compared with that of a pebble-mill, instead of a ball-mill, perhaps accounts for the remarkably good results, which are difficult to understand at first glance. Students of the mathematics of crushing should analyze for us the forces acting through this mill, of which we shall doubtless hear further, as the reported results indicate that the machine has a future.

In mill design other than crushing, the trend to

counter-current decantation has continued, at the expense, in great measure, of the basket types of filter. Thickeners of the tray type are proving very valuable. At the Liberty Bell, crucible smelting of precipitate, with preliminary sintering, has been put upon a rational basis. Weinig's description of the method merits consideration, particularly from the operators of relatively small plants.

Iron and Steel in 1916

The "prince or pauper" industry outdid itself in 1916. It became a prince in 1915, but what title to give it for 1916 we do not know. It was not a dictator, for it is commonly said that the tremendous price advances that occurred were brought about by the buyers, not the sellers, through the buyers importuning the mills to place their orders on books, even going to the length sometimes of requesting that the orders be entered and the price be set against the tonnage when it suited the convenience of the mill. "Delivery at mill convenience" became a common phrase in market reports.

Using weighted averages, the advances in pig iron per gross ton and in finished steel per net ton, have been as follows:

	Pig iron	Steel
1915	\$5.50	\$13.00
1916	11.00	29.00

Steel prices reached by the end of 1915 represented the traditionally "safe" level, the level attained in 1907, but not reached in the advancing movements of 1909 or 1912, though they were substantial and satisfactory movements in their time. Immediately, or as a matter of fact on Jan. 6, 1916, there was published the "stop, look, listen" statement of Chairman Gary of the United States Steel Corporation. Whether he expected his advice to be heeded, or merely wished to wash his hands of responsibility for what should occur thereafter, is not known. At various times in the past the Steel Corporation has applied the brakes, as it has sometimes also supplied an accelerating influence.

Steel price advances in 1916 were most rapid in January, February and March, and in August to November inclusive. There was almost a lull between times. The market showed its usual signs of possessing inertia, whether static or kinetic. Circumstances were such as to arouse some suspicions that an advance in steel bars made Aug. 1 by a prominent steel company represented an effort to get things started again. The bar market has shown some indications of weakness in July. If it was an effort, the effort was successful.

The 1916 advance in steel products brought prices late in October level with the top prices reached in the "boom" of 1899, but the prices taken for 1916 are prices for delivery at mill convenience, while in 1899 there were no such prices, the market being substantially a premium market. Prices advanced nearly \$10 a ton more, at any rate, and all that was clear space on the chart of prices for the steel industry's whole history, covering a period of only about a quarter century, as it was early in the decade of the eighteen-nineties that

mild steel supplanted the product of the puddling furnace as the dominant rolled product. Rail carbon steel had, of course, replaced wrought iron for rails much earlier, but it offered a vastly superior commodity, beyond question in any quarter. Comparing steel bar prices at the end of 1916 with historic iron bar prices, one finds as high prices, or higher, only from September, 1879, to April, 1880, and in various periods prior to the spring of 1874. The high priced period which ended in 1874 has lasted for about a decade.

We estimate production in 1916, in gross tons, as follows, compared with previous records:

	Estimate 1916	Former Record
Pig iron	39,400,000	30,956,152 (1913)
Steel ingots and castings.....	42,500,000	32,151,036 (1915)
Rolled steel	30,500,000	23,112,986 (1913)
Rolled iron	1,500,000	1,678,257* (1913)

*Surpassed in various preceding years. Record unknown.

Pig iron broke its former record by 27 per cent, while steel ingots and castings broke their former record by 32 per cent. The divergence was due partly to the iron founding industry being not proportionately as busy as the steel industry in 1916, and partly to the fact that owing to the manufacture of a large tonnage of shell steel, with heavy discards, there was more scrap available and less pig iron was needed. The proportion of rolled steel to ingots produced was lower in 1915 and 1916 than in normal years, for the same reason, and as 1915 was not a sure criterion of the disturbance in proportions produced the estimates for 1916 must be taken with a larger allowance than is usually necessary. Approximate estimates are useful as the official statistics will not appear for months.

Not a single new blast furnace was blown in during 1914, and there were only three for 1915. As only 31,000,000 tons of pig iron had been produced in 1913, although the industry ran substantially at capacity through the first ten months of the year, there was a disposition to rate the actual productive capacity, at the close of 1915, at not more than about 35,000,000 tons. Although only two new furnaces were blown in during the first half of 1916, and only one or two in the second half, the actual production exceeded the estimated capacity by more than 10 per cent. This performance is attributed chiefly to changes made in the lines of many furnaces, chiefly by way of enlarging the hearth, though progressively harder driving year by year, and minor improvements, have played their part.

The excellent performance of the blast furnaces averted the pig iron famine that had been predicted for the early part of 1916. It had been noted for a number of years that steel works capacity was increasing much more rapidly than blast furnace capacity, measuring the latter merely by the number of new stacks. It was about June, 1915, when the market movement was still in its infancy, that the first announcement was made of any fresh increase to be made in steel making capacity. Afterwards the new projects came thick and fast. Fully 3,000,000 tons of steel ingot capacity was added in 1916, and there would have been more had not construction work proceeded so slowly. There is fully 4,000,000 to 5,000,000 tons of capacity now under construction or

definitely projected, with almost as large a tonnage of blast furnace capacity.

The perennial question has been "Where does all the steel go?" This question has been asked in times of depression, when there seemed to be no demand at all, for in the poorest steel years the output has exceeded that of seven years earlier, and usually it is asked also when demand is heavy. In 1916 "war demand" appeared to most observers to furnish an adequate explanation, but that was hardly the case. The rolled iron and steel exported directly, or consumed in the manufacture of everything that was exported, railway rolling stock, machinery, loaded and unloaded shells, etc., was approximately 8,000,000 tons, or 25 per cent of the production. In 1912 and 1913, the best export years, the proportion of export material was about 11 per cent. The remainder, for purely domestic consumption, was about 22,000,000 tons in 1912 and 1913 and 24,000,000 tons in 1916.

In some quarters the domestic consumption was relatively light in 1916. Cars and locomotives ordered in 1915 and 1916 were much fewer than in several of the earlier years, when the steel making capacity was much less. Monthly reports of the Bridge Builders' and Structural Society showed average bookings in 1916 representing 70 per cent of the fabricating capacity, distinctly a poor record. The production of galvanized sheets was very light. The production of rails for domestic consumption was much less than in 1912 or 1913. The consumption of the ordinary every-day commodities, the things the people at large use, as distinguished from consumption by the railroads and consumption in great construction works, must have been very much larger than in any preceding year. There was a reason for this. Most of the people had plenty of money, while the capitalists did not care to invest heavily, against the prospect of future earnings, at a time when materials and labor were extremely dear.

This analysis naturally suggests the future. By the middle of December the iron and steel market had slowed down, had almost come to a halt, due probably to a combination of circumstances rather than to the single incident of Germany making a peace overture. There is more interest in the future. The present appears to be a case of filling the large mass of orders on hand, with the country's transportation system in very poor working order, car shortages almost everywhere and embargoes without number.

After the war, whenever that period starts, there will be different prices, prices more or less in keeping with the conditions expected for a number of years. Projects long deferred will be launched. The past three years, at least, have constituted a period of very light new construction, and requirements have banked up.

Niagara Falls in 1916

To those who realize the intimate relation of electrochemistry to our daily life it is no matter of surprise that the past year was one of extraordinary activity in Niagara Falls and that its development as the greatest

electrochemical center in the world reached a maximum. Not one of the electrochemical factories at Niagara failed to feel the stimulation of the increased industrial activity throughout the country.

It would be difficult, perhaps impossible, to say what particular industry was affected most. A mere study of prices would at once show what the conditions were as regards products like aluminium, ferroalloys, chlorine, etc., but there are other products in regard to which prices do not give any indication of the extraordinary developments, such as abrasive materials, graphite and carbon electrodes. Nor again would the price list show the new plants started at Niagara Falls.

There is perhaps a tendency to believe that this great activity in electrochemistry has been mainly due to war orders, perhaps because of the considerable popularity given to accounts of the importance of electrochemical products as a factor in national defense. However, while a certain percentage of Niagara Falls products in 1916 may be classed as direct war orders, the great bulk of the increased production was only related in an indirect way to the war. It would, of course, be folly to pretend that the enormously increased prosperity enjoyed by the electrochemical industries was normal and would have existed quite apart from the war; but it is true that the greater part of it has not been due to mere war orders, but was simply inevitable because of the general increase in prosperity throughout the country.

The truth is that there is no industrial center in the country which is more intimately associated with the daily life of every man in the United States. The laborer, the farmer, the clerk, the banker, in fact every simple inhabitant of the United States, is closely dependent on the electrochemical industries of Niagara Falls every moment of his life from the time he leaves his bed till he returns there at night. Unfortunately this dependence on electrochemical products is by no means realized by the man in the street. He does not know that in his every-day life there is hardly a moment that he is not using something directly or indirectly a product of the electrochemical industries, and that the production of this product depends on the utilization of what he has been taught to believe is a great "national spectacle" of right belonging to him, but threatened by a mysterious monster called a Power Trust.

We have said that the Niagara Falls industries have reached a maximum because it is now too plain that the curve of progress must become a horizontal line or even deflect downwards. With the increased production of electrochemical products in 1916 there has been a corresponding increase in the demand for power and long before the close of the year the limit allowed by the so-called Burton Act was reached. True the Burton Act was dead and the power of granting further diversion of water was in the hands of the Secretary of War; but unfortunately he was doubtful of his right to exercise the power, and his doubts were probably strongly reinforced by the fear of popular

superstitions deliberately fostered by unscrupulous propagandists.

The serious situation resulting from the power shortage was further increased by the demands of the Canadians. Here, too, there was an enormous increase in the demand for power in 1916 and the government was asked to exercise its right to cut off the supply of power exported from Canada to the United States.

Thus, while the year 1916 has witnessed a wonderful growth in the Niagara Falls electrochemical industries of which the country may be justly proud, it has also presented the sad spectacle of this great and beneficial development threatened with arrest largely for the purpose of keeping a Harrisburg printing press busy.

Electrometallurgy in 1916

During 1916 there has been a greater commercial development of electrometallurgical industries in the United States than at any time during recent years. What we said of the Niagara Falls electrochemical industries—that their immense activity and prosperity simply reflected the broad industrial activity of the country—is also true of electrometallurgy, and again in this case some direct influences of the European war are easily discernible. The heavy consumption of alloy steels formerly made largely in the crucible, the increased demand for ferro-alloys caused by the greater production of alloy steels, the shutting-off of imports of ferro-alloys and other electrometallurgical products, like aluminium and magnesium, the high prices of metals permitting experimentation with new processes—all these are contributory causes of the recent industrial advance in electrometallurgy.

After the installations of electric steel furnaces in this country had approximately doubled in 1915, the progress of the electric steel furnace has continued at almost undiminished rate in 1916. The chief trouble met with is a lack of experienced operating men. But high-speed tool steel is now being manufactured in 6-ton heats as a regular procedure, in contrast with the 100-lb. pour of the crucible. The heavy demand for high-speed tool steel and the difficulty of securing crucibles at any price has made the electric steel furnace an economic necessity, and it is here to stay.

A considerable number of electric furnaces have been installed in foundries for the manufacture of steel castings. More installations are contemplated involving the use of the electric furnace in a duplex process with the open-hearth or the converter. Several electric furnaces are melting ferromanganese before addition to steel.

In Germany—formerly the largest producers of electric-furnace steel—the heavy demand for tool steel has also resulted in an increased use of the electric furnace for steel making. In August the production reached 17,000 tons per month, or six times the monthly production at the outbreak of the war. On the other hand, the production of crucible steel in Germany has remained stationary, there being no new installations of any size. The monthly production of electric-furnace steel in Germany is now double the crucible output.

On a smaller scale there has been a heavy increase of ferro-alloy manufacture in the United States. Three new manufacturers of ferrosilicon started production during the year. At the outbreak of the war about half of the domestic ferrosilicon consumption was imported, but now practically all ferrosilicon needed for consumption is manufactured here, and a small amount is being exported. To provide part of the needed furnace capacity a calcium carbide plant in Niagara was switched over to ferrosilicon manufacture. During the period in question the domestic consumption of ferrosilicon has doubled and is estimated at 45,000 tons annually.

The largest domestic producer of ferrochrome was able to supply the increased needs of the steel industry, but it is probable that if this producer had not carried large stocks of foreign ore, there would have been a shortage of ferrochrome. The development of California mines has been slow and the average grade of the chromite was too low for alloy manufacture. With other alloys, such as ferrotungsten, ferrovanadium, ferrotitanium, and ferromolybdenum there has been an increase of production and several plants have been established. There is now sufficient plant capacity in this country for filling all domestic requirements of ferrotungsten, and for the first time considerable quantities of ferrotungsten are being exported. Exports of ferrovanadium have doubled since 1915. Most of the new producers are using the electric furnace. Ferrotitanium is produced at Niagara to the limits of plant capacity and the demand is greater than the power supply. A fair quantity of ferromolybdenum is being manufactured in the United States, and toward the end of the year there was a marked increase in demand for foreign shipment which is believed to have to do with the lining of big guns. Ferro-uranium was produced commercially for the first time in this country, and may be added to the new products of the electric furnace.

Aluminium manufacture in the United States enjoyed in the past year undoubtedly maximum production and maximum prosperity in its history, the lead over European producers being increased. The North Carolina plant of the Southern Aluminium Company, which in 1915 passed into the hands of the Aluminum Company of America, is expected to start operation in the near future. Further large projects for increased plant capacity are under way. The imports dropped to about one-tenth of the normal quantity and exports doubled. There are no new producers besides the Aluminum Company of America, up to the present. J. W. Richards, perhaps the best connoisseur of aluminium metallurgy, estimates that by 1925 aluminium will be third in importance among metals (measured by weight), and will be outranked only by copper and iron. This is an interesting prophecy, and a safe one, too, as 1925 is sufficiently far off. Qui vivra verra.

As a result of operations started in 1915 several plants are producing on a small but commercial scale by electrolysis very pure metallic magnesium.

Among new electrometallurgical enterprises electrolytic zinc looms large. There is the electrolytic zinc

plant of the Anaconda Copper Company at Great Falls, Montana, with a production of 100 tons of electrolytic zinc per day, while as a result of the Bully Hill experiments of the General Electric Company a \$350,000 electrolytic zinc plant is being erected at the Mammoth smelter in California. As in 1915, there was in 1916 practically no development of electric-furnace smelting of zinc ore, so that in a time most opportune for commercial development nothing has been accomplished. It would seem that electrolytic zinc has the upper hand, and may be able to keep it, although in a measure its sudden development to a commercial process has probably been accelerated by the facilities of the Anaconda company available for placing an experimental development on a commercial basis.

The electrolytic copper refineries that were hit so hard at the start of the war have all been working to the limit of their capacity. Electrolytic refining has also made a success with tin; for years we have heard from European tin producers that Bolivian tin ores would always be out of question as the tin produced would be too impure; the success of the combined tin smelting and electrolytic refining plant of the American Smelting & Refining Company at Perth Amboy has proven that the additional refining cost is by no means prohibitive, and the only reason why enlargements have not yet been made is the present high cost of building materials. The plant is to stay and to grow.

The Front Office

He is a successful chemical engineer and is called upon for advice by the great and powerful. Neither contact with the affluent nor his need of a larger safe-deposit box for his growing bundle of securities has turned his head. Success has mellowed him, made him more thoughtful of the general welfare and caused him to grow in grace and amiability.

It was at the end of a long and very hard day. "I think," said he, "that if I had the administration of a great corporation in hand, I should ask for a special appropriation of ten thousand dollars a year in order to provide two five-thousand-dollar men. And I should put one out in the front office to meet visitors as they come in and the other should answer the telephone. I think it would be a profitable investment.

"Lately I wanted to buy some property. One of the big corporations with stock duly listed on the Exchange owned a factory site for which they had no use and which they were anxious to sell. It was just about what I wanted. They had been trying to sell for several years, and I doubt if many bids had been received. So I went to see them. Now I do not set up to be Phoebus Apollo or Hermes, or even a handsome man, but I do not think I look like one bent on robbing safes. Yet if I had been a tramp or a yegg I could not have received a less cordial reception. There was a very glib young person in attendance who acted—no matter what he thought—as though his chief duty was to get me to go away. He did not know anything and could not understand explanations. In vain I urged him to bring me into communication with an officer of the company.

My reasons did not satisfy him. Finally I broke through his barrier and went inside, just a little flustered, but not too nervous to lower my bid. They were still very anxious to sell, and were very glad to see me. But why insult me on the way to see them?

"Again, the other day, I was in the market for a product that just now is produced in large quantities, but most concerns are sold out ahead. I called up one of the chief producers, gave my name, and asked as politely as I could. They know that I am often in the market, so it would seem that I ought to be a welcome guest sometime in the future. I explained what I wanted and what deliveries I needed, but 'Sold out. Nothin' doin'. Click,' was the answer that I received, and the last word, click, was a noise made by hanging up a telephone receiver; it was not a spoken word. I do not want them to kowtow before me, but I do like a rather full answer to questions. Rebuffs like that upset me and make me want to avoid communicating with them again if I can help it."

The fact is, the front office needs reorganization in a great many establishments. The men in authority are busy and do not want to be bothered. The ill-paid homunculus that sits at his desk outside the inner sanctuary does not want to disturb them lest he incur their ill favor. But the man from without bringing good will and business is put through a distressing initiation before he can enter the sacred portals of the place where goods that he may want to buy are for sale.

The front office homunculi or the elderly dunder-heads in buttons and the braying asses at the telephones may all be useful animals, but they are not in their right places.

They should be supplanted by men (or women, for it's brains, not sex, that we are discussing) who are polite in their minds, who are able to apologize with grace to the man whose temper is undergoing exhaustion by long waiting, and they should know enough about the business to save half the waiting now necessary.

If we were to give the names of the great and otherwise well-managed concerns which maintain a veritable Bureau of Insult in their front offices and at their telephones we might easily be sued for libel. The captains of industry, at their desks a few doors away in the same offices, seem to use up all the politeness in their commercial servants. They are not aware of the naughtiness with which they even up their self-esteem upon visitors.

The small buyer, whose needs are as important to him as are those of the thousand-ton man, has no chance at all. When the war is over he will go back to the importer. The importer will make him welcome, and the small buyer will not find a single big head in the importer's office during business hours.

Politeness coupled with ability is scarce and expensive, but in the case of young persons who have the ability but not the gift of gracious bearing, there used to be methods current to put what was termed the fear of God into their hearts. It might be well to revive the custom.

Mexico—What Will the Final Outcome Be?

(From an American Engineer, for Years in Mexico.)

To the Editor of Metallurgical & Chemical Engineering

Sir: What will the final outcome be in Mexico? This is an interesting question to many people, though not to any large proportion of the American people. To us Americans in Mexico who have material interests the question is not only interesting—it is important. Whether our going there to carry on business was an offense against public morality or not, the cold fact that our money and our properties are tied up there concerns us vitally, and we wonder what we can do toward conserving our interests.

It is impossible to discuss the commercial aspects of the case without bringing in the political aspects. There has been as much political bungling of relations with Mexico as there was between Bulgaria and the Entente Allies—which permitted Bulgaria to take sides with the Central Powers. Mexico has wanted for years to get on a friendly footing with the United States, and Americans who have gone into Mexico during the last ten or fifteen years have done their best to convince the Mexican that that old feeling of distrust toward Americans was unwarranted and uncalled for. It has worried the Mexican to see all the commerce and the active industries of his country going into the control of foreigners; and he has had an innate fear that some day the material influence of the domination of commerce would lead to the desire to exert a corresponding influence in political affairs. So he has distrusted the foreigner in general, and has singled out the American in particular mostly because of personalities.

When we pin down any Mexican to tell us what the real fundamental causes are or have been for the universal feeling against Americans more than against other foreigners, he is hard put to explain himself; he must speak of personalities, and his delicacy makes him hesitate to speak out. He will admit that any American-managed institution will operate in conformity with the laws of the country, will pay its employees better wages, will give them more hospital services, and more schools for their children, and will abstain from mixing in politics more so than concerns managed by other foreigners. Then what is the trouble?

Well, says the Mexican, you do not understand us personally, our customs; you look down on us with scorn, and force on us your beliefs that we are an uncouth, undesirable people, not to be considered your equals in any phase of life. You show it explicitly in that you will not intermarry with us. All other foreigners will marry here, but the American, as a whole, seems to have decided scruples against it. On our side, we think that Americans are brusque, blunt, cold-blooded, too clever for us in business, impolite, lacking in culture and refinement.

The American in Mexico realizes the handicap under which he labors in that the Mexicans as a whole have an aversion to the Americans as a whole, so he endeavors to overcome it by patient, tactful manner in his dealings with the Mexicans. But it is against the lifetime customs of the American to have to use the special tact needed in Mexico; at home he uses special-delivery mail, the telephone and the telegram to expedite his business with brusqueness and rapid-fire decision; this bores the Latin-American at every turn. So

many an American in Mexico makes but a sorry mess of it, and usually makes himself more disliked than ever. The Americans who have been a long time in Mexico have improved themselves in this detail; their experiences have taught them to do it. But the newcomer and the people at home show no improvement.

"Foreign policy" is a term or expression as foreign to the mind of the average American as is the term "tact." At home we think the sun rises and sets around our good old United States; all foreign peoples should learn our language and should be glad to have our business on our own terms. The American who goes to a foreign country condescends to learn about as little of the language of that country as is absolutely needed still to bat around at his business, comprehending little and miscomprehending much of the language, ways and customs of the natives.

So the average newspaper writer, associated press correspondent, confidential agent, personal spy and all of the ilk, are as competent to understand the Mexican question and to write reports on it as would be some Hungarian journalists that could speak no English and had never been in the United States, should they be sent over to write up the negro question of the South.

Porfirio Diaz knew that Mexico's natural resources would never serve the upbuilding of the country if native capital were to be depended on for the exploitation. He deliberately planned and carried out a program that induced the coming of foreigners and of foreign money into the country. Among the foreigners were many Americans. Foreign governments at the same time materially aided their nationals to come to Mexico to do business. Among these foreign governments the American government for thirty years encouraged its nationals to go to Mexico. The United States Federal government has brought about the building of the Pacific railways by the scheme of granting lands and other natural resources to the railway builders. The time for the necessity for such measures has passed, but there was a time when it was necessary. Mexico also has aided the building of railways by using the same plan. In the States we spoke of "land grants," in Mexico they are called "concessions."

To-day, in the States, when some corporation looks over the field for an opportunity to set up a factory of some kind, all the towns in the territory considered get busy and offer free land and tax exemption in order to secure the location of the factory. The scheme is considered honorable and to be commended. When Porfirio Diaz wanted cotton factories built up in Mexico he followed the same plan, but our American people and our home government qualify those acts of his as acts of giving away the country's resources, and the factory builders are called concession hunters and public grafters, and it is argued that these people should ask for no sympathy should they lose their interests later on.

I have lately been in middle Pennsylvania, and I observed many silk mills, all owned by one parent company in Germany. The mill managers and superintendents are German; many of their skilled operatives are German. Every new mill installation receives free or nearly free land for building sites; all have received tax exemption. Did Germany's home government encourage the building of these institutions? Did she discredit her citizens because of their enterprises? Does the American government encourage such build-

ing, and does it, or do the American people discredit these Germans because of their coming over here to do business?

Then why are we Americans of Mexico so discredited, so berated, for having gone into Mexico, subject to the laws of Mexico, just as those German capitalists and German operatives came to the States? If for thirty years the Mexican government has encouraged us to come to Mexico, and for the same thirty years our own American government has encouraged us to go to Mexico, does our own American government not owe us now a proper consideration? Does the particular feature or incident that Mr. Woodrow Wilson is now President absolve the American government from its moral and material obligations to us that have resulted from a thirty years' continuous policy of encouraging American commerce in Mexico?

It is an outright misrepresentation of facts to say that the exploitation of natural resources and of ordinary commerce in Mexico by foreigners is as a whole based on "concessions" or improper privileges that operate to bleed the country for the undue benefit of the foreigner. There may have been an occasional instance in the earlier years of Mexico's development, just as there may have been in the States, when undue profits were made. But 98 per cent of the "concessions" given in Mexico are as just and as conformable to the laws in vigor as can be found in the States. The crass ignorance, the petty pigheaded indifference of our home people and our home government to the correct meaning of the word "concession" as used in the Spanish language excites our derision. In the States a corporation secures a "charter" that gives legal permission to operate the expected business under the restrictions placed by law. A peanut vendor must also secure his legal permission, and it will be called a "permit" or "license." In Mexico these same permissions would be called "concessions" and would have honorable significations; but the American signification of the Spanish word "concession" infers something dishonorable. This idea has really become an obsession in the States.

We Americans derive much amusement from deriding the German "Kultur." Probably their "Kultur" is open to derision and censure. But the new American "Kultur" lately expounded by our home people and government—"that the flag does not follow an American when he goes to a foreign country"—is many times more despicable, more unworthy of a great nation. And we think it is really dangerous for the welfare of the nation.

All this is said in an endeavor to demonstrate that the American with material interests in Mexico is entitled to the good will, the moral support, the material support and the protection of his home government. Besides this, the American government has arrogated to itself the supervision of the affairs of all foreigners in Mexico, and will therefore have to render accounts some day to all foreign governments.

Our money is invested in Mexico; our business is not going on; our holdings are being injured because the existing authority in Mexico is persecuting our holdings with an apparent view of forcing us to abandon them completely and thereby suffer financial ruin. They do not clearly confiscate, but they do actually sequester our properties. Shall we quietly submit to conditions and let everything go by the board? Shall we try to meet every day's new, arbitrary decrees calling for more and more ready cash put in, so as to try to see the game through until the extortion be satisfied and we be permitted to carry on business under legitimate conditions?

It is hard to decide. Undoubtedly all institutions of limited financial resources will be hard hit, and many

of them will be ruined. The big, strong concerns will die harder.

Is there any hope that the Carrancista organization will be able to establish finally a stable government and bring peace to Mexico? None whatever. They are as able and competent to govern Mexico, and as deserving of the good will and support of good people, as the Industrial Workers of the World would be if given a chance at governing the United States.

Can Villa ever come back, and could we put any hopes in a government that he might establish? No. Villa lost the chances he had when he became his own true self and tried to assault the young French lady in Mexico City on his entrance there. The painful fact that he could never "be," any more than Huerta could "be," was forcibly brought home to President Wilson by the French Government's outright declaration. The next problem for President Wilson was that of finding a pretext for disowning Villa without letting the gentle public know the regrettable reason. So we have the statement that when later the famous call was made to all combatants to come to camp to settle their differences, the Villista chieftains answered: Agreed. The Carrancista chieftains answered: Agreed, but in the end we shall agree to whatever our First Chief shall decide. Wisdom of Solomon. Villistas are but individual parties bound together by but a gentleman's or bandits' agreement. Carrancistas have formal organization, discipline, and are therefore entitled to preference. Decision by the Court: Recognize Carranza with all the pomp and ceremony of war.

Was there any rhyme, reason or sense in any one's being recognized? It appeared to be thought that simple "recognition" was all that was needed to stabilize any government in Mexico. The American government seemed to think that its recognition would make or unmake any old government. We have seen that its recognition of Carranza has not made nor can "make" his government. We saw that its withholding or recognition of Huerta made much trouble for the old man, and possibly did "unmake" him; though we are inclined to believe that the thousand-and-one ways employed to hamstring Huerta were what really "unmade" him.

Can Feliz Diaz carry through a successful revolution and establish a stable government? Not with the limited backing that he appears to have. If he were a real strong man and of personal resource he might make quite a bid for it.

What about Zapata? Zapata is a bushwhacker, pure and simple; a four-flousher, and a very poor aid in military sense, as Villa found from experience. But it will call for the services of the Apache Indians to make a thorough job of finishing him.

Can Carranza retain control of the government and also physical possession of the country in face of the combined opposition of Villa, Zapata, and Feliz Diaz? He cannot, unless he can obtain the material as well as the moral backing of the United States; and material backing must mean loan of sufficient money.

Can Carranza obtain that material backing? It is unsafe to guess at what President Wilson may do in the matter; he has shifted, side-stepped, back and filled, and eternally hesitated on the Mexican question until no mortal man can guess at what he may do next. I think that we can hazard one guess at one feature, and that is that if in the course of human events it again comes up to him to recognize or not to recognize some man as President of Mexico, he will immediately and in a loud voice declare that he will never, no never, recognize any man as President of Mexico.

Assuming that President Wilson exercises no particular initiative on the subject, can Carranza get the necessary loan? Not until his government adjusts it-

self to civilized customs; and it is improbable that it can do that, because its adherents, in the main, are so radical and arbitrary, and so hard to control that it is unlikely that it would be permitted to carry through any healthy, moderate program that it might wish to.

What effect has the European War on the Mexican question? It is commonly conceded that since the war came on it has been sufficient reason for refraining from radical action toward Mexico. But it is like the Irish question—when the war ends, the question will bob up again.

During Huerta's tenure of power, which was for a year and a half preceding the opening of the Great War, with all great nations, excepting the United States, having recognized Huerta, with all foreigners in Mexico vigorously protesting to their home governments about the state of affairs—the stock answer that other nations sent back to their nationals in Mexico was, "that your home government regards it as your patriotic duty to submit gracefully to what is going on; do it to aid your own country's best interests. The American Government's policy toward Mexico is producing results that we never before dared hope for. Its loss of prestige, and the resentment aroused throughout all Latin America are exceedingly pleasing to us. Its loss is our gain."

And to think that that state of affairs has continued for two and a half years more, and the end is not yet in sight.

Assuming that the European War continues for four years more, and that President Wilson makes no change in his Mexican policy, what is likely to occur in Mexico?

Disintegration of the Carrancista government; short-lived attempts by other men to take Carranza's place; growing power of Villa and of Feliz Diaz; more bushwhacking by Zapata; total anarchy in economic affairs and industry in general; more and more losses by foreign interests. And when the limit of endurance has been reached, the foreign, material-interests people will for the first time enter into Mexican politics; will organize for particular interests of Villa, of Feliz Diaz, of the old-time, respected Porfirio Diaz people, with a considerable proportion of foreigners in active service, into a compact, well-equipped organization that will sweep Mexico and will establish a government so strong and so stable that our present American dream of dominating politics from the Equator to the Canadian line will never come true.

The Recovery of Molybdic Acid from Phosphorus Filtrates

To the Editor of Metallurgical & Chemical Engineering

SIR:—The following method has been used by the writer for the last two years and has proven quite a saving, considering the present price of the reagent.

The filtrates from the determination of phosphorus are saved in a suitable container, microcosmic salt is added, and from time to time as the solution increases in volume it is tested to see that sufficient phosphate is present to throw down all the molybdate. When considerable yellow phospho-molybdate precipitate has accumulated decant off as much of the clear liquid as possible, and then filter off the yellow precipitate using suction, and wash several times with dilute nitric acid and then several times with water. Suck the precipitate as dry as possible. Now take a small weighed portion of this precipitate and dry at 105 deg. C. to determine the amount of moisture in it. After the moisture is known weigh out enough of the moist phospho-molybdate so that it contains 115 grams of the dried precipitate. Place this precipitate in a liter flask or

beaker, add 100 c.c. of water and 100 c.c. of ammonium hydroxide and warm to about 80 deg. Stir the contents of the beaker thoroughly and if all the precipitate does not dissolve add ammonium hydroxide slowly with stirring until all has dissolved.

Cool this solution under the tap and add 150 c.c. of ammonium hydroxide and then a saturated solution containing 10 grams of magnesium nitrate. Shake vigorously several minutes and then allow the precipitate of ammonium magnesium phosphate to settle over night. Filter with suction, sucking the precipitate as dry as possible. Make this filtrate up to 750 c.c. with water, cool and add it to a cooled solution of 625 c.c. of water and 625 c.c. of nitric acid. The reagent is now ready to be used to precipitate phosphorus from solutions.

The precipitate of ammonium magnesium phosphate is dissolved off the plug with dilute nitric acid and the acidified solution is added to the container in which the waste filtrates are kept, and in this way less microcosmic salt is necessary for throwing out the molybdate for further recoveries.

Valence and Valence

To the Editor of Metallurgical & Chemical Engineering

SIR:—After reading the article entitled "Inadequacy and Inconsistency of Some Common Chemical Terms," by Carl Hering, on page 649 of your journal (Vol. XV, Dec. 1, 1916), I looked the matter up in some of the current textbooks of general chemistry and was more than surprised at the meagerness and looseness of the treatment of the topic of valence there exhibited. The subject is discussed so thoroughly and the principle is used to such an extent in the chemical instruction given in the courses at the Michigan College of Mines, under the supervision of Dr. C. M. Carson, that I had not imagined that the matter of valence would be handled so lightly elsewhere.

This condition of affairs exists probably because the importance of the concept of valence is not widely appreciated. And in this connection it might be well to suggest that the majority of the teachers of chemistry would welcome more frequent expressions of the opinions of chemical and metallurgical engineers relative to the greater or lesser importance to be assigned to the various features in courses of instruction in chemistry. One effort along this line resulted in the editorial on "Fashion and Style in Chemistry," on page 501 of your issue of Nov. 1, 1916 (Vol. XV).

In the instruction given at this institution the word valency is used to denote the more or less variable capacity of an atom of an elementary substance to combine with an atom or atoms of other simple substances as exhibited in its known combinations. No qualifying signs or numerals are applied in connection to this general property word. But such signs and numerals are applied in connection with the term valence which is defined as the kind, in terms of polarity, and the amount of the chemical combining capacity of an atom of an elementary substance, as manifested in the given case, relative to the combining capacity of the atom of the standard substance, hydrogen, to the atom of which a positive valence of one is assigned.

Here the concept of valence is used to enable a student to write the formulas of all possible normal salts without the excessive use of the memory that would otherwise be necessary. Most equations are balanced by a modifications of the valence method of O. C. Johnson. And the relation expressed in the equation—chemical equivalent $\times$ valence = exact atomic weight—is made use of in the calculation of these quantities. In the

electrochemical work the correspondence between valence and the ionic charges is emphasized and applied. Exercises and problems involving these ideas are given in sufficient number and variety so that the concept of valence can become a really useful tool.

It is only in the case of persons with sharp impressions requiring modification that there is any difficulty about the introduction of a new word to replace a less comprehensive one. If the terms reduction and adduction are properly explained and illustrated in the first instruction that a student receives in chemical work, he will have no subsequent difficulty in keeping them in their proper places alongside the less general terms deoxidation and oxidation. The use of the following scheme, shown as applied to chlorine, has been found helpful in instruction of this kind:

Valence change in adduction reactions.

Valence change in reduction reactions.

The Protection of Iron and Steel

To the Editor of *Metallurgical & Chemical Engineering*

SIR:—In a paper read last September before the American Electrochemical Society it was brought out that the coating metal must be electropositive to the metal to be protected. If the coating metal is electronegative, then the slightest break or pin hole in the coat will allow moisture to set up a galvanic couple; the iron or steel will then not only rust, but corrosion will go on at a greatly accelerated pace.

That is why tin, lead, brass, copper and nickel are all very poor protectors against the weather. These are all electronegative to iron or steel. The only available electropositive metal is zinc.

Unfortunately zinc is brittle and unless great care is exercised to not crack it, split, or foliate it, when working the coated articles, it leaves relatively large areas unprotected. It is not always feasible to redip or replat the articles after surfaces or seams have been damaged by bending, riveting, calking, etc.

Alloys of zinc with tin and lead are tough. Unfortunately it is difficult to put them down. In the hot bath the alloys have a tendency to segregation that is so serious as to demand great accuracy and care in securing and maintaining just the proper heat, not only in the bath, but also when the coated article is cooling; otherwise the brittleness of the zinc supervenes; when segregation has caused areas to be coated with the separated-out lead or tin, these areas are not zinc-coated and therefore as subject to rapid galvanic corrosion as though no zinc were used, but pure tin or lead.

A relatively new coating process is fortunately available. Zinc is reduced to a very fine powder, containing very little oxide or other impurity. This is mixed with a suitable flux to the consistency of a creamy paste that is applied cold with the brush, by dipping or spraying. The metal to be protected is, of course, first cleaned as it is for any method of protection. The article is then heated in any convenient way slightly above the melting point of the zinc. It is obvious that the means of putting on the cold Epicassit (the name given to the process) or the means for heating are relatively immaterial to the result, but governed chiefly by convenience, character and quantity of the article.

In order to secure a very tough and therefore ductile coating that will resist bending, twisting and hammering without cracking or splitting off, tin and lead are added

to the pulverized zinc. The segregation found in large baths is absent, as the coat is, of course, very thin as compared with a bath. Nor can there be segregation as the coat is melted down, because the particles of zinc, lead and tin powder are separate and not alloyed as a rule; these particles are so small that the protective electrogalvanic action of the zinc extends to the adjacent lead and tin particles as well as to the iron or steel underneath. Epicassit-galvanized articles have much more of the bright, smooth character of tin plate than is the case with pure zinc.

This method is equally useful whether employed initially for entire surfaces or whether used to repair damage in galvanized work, whether caused by time or in field assembly. The coat may be applied externally or internally, over whole surfaces or only to certain areas. The articles may be coated by being brush-painted with the cold epicassit, by spraying or by dipping. The application of heat has just as wide latitude; baking ovens, heated tumblers and the blast torch are used. Any of the softer metals that can be reduced to a fine powder are used as pure tin, pure lead, pure zinc and their mixtures in various proportions. While it is but little demanded, it is entirely feasible to apply dissimilar coatings on the inside and outside of vessels.

One of the chief uses of Epicassit is that referred to of providing a very tough and adherent coating of zinc of great latitude as to method and ease of application.

A Chemist's Vacation

By Edward Hart

Visiting time had come. For forty years I had taught and given much of my time to others. Now vacation days had dawned. No longer must I face a round of lectures, quizzes and the daily drudgeries of the teacher's task. I packed my grip and started south.

In the days when Dr. Mallett and Dr. Prescott and Henry Carrington Bolton and William McMurtrie were still with us, we had come together every summer as Section C of the American Association for the Advancement of Science, and in the evenings with others as Section Q—not announced on any calendar of our meetings. In the daylight we told chemical stories and in the evening others. Now the select company had grown until it seemed like a mob. I missed the old faces and longed to see them once more.

I reached Washington in the evening and after dinner made my first call on Farmer Wiley. He was, as befits a farmer, in his shirt sleeves with an apron around his slim waist making sausage. Mrs. Wiley was assisting and I joined the party. We made 24 lb. of sausage, good sausage. I ate some of it next morning—and talked; how we talked!

Next morning, I looked up Frank W. Clarke and listened while he told me about the composition of the skeletons of those living in the sea and the geologic conclusions to be drawn. And I responded, dilating upon the green sand of New Jersey, how I had discovered that it consisted of about 60 per cent common quartz sand each grain covered with 40 per cent of green glauconite. Then he read me this poem written in his early days:

THE POLITICIAN'S PRAYER.

By F. W. CLARKE.

Our Father—whether in Heaven or Hell
We hardly know—
Look down (or up) to where we dwell,
And while our supplications swell,
Thy gifts bestow.

Give us the counting of the votes
Election day,
Let none of our men turn their coats,
But send the opposition boats
Salt River way.

Let slander, malice, fear and fraud
This autumn fall!
But if such tricks should be abroad,
Expose our enemies, O Lord,
Let ours prevail.

If base repeaters cheat the polls,
Their crimes betray!
Strike terror to their guilty souls!—
But write their names on Mercy's rolls
Who vote our way.

Give us by honest means success
In all this fight;
But if misled by bitter stress,
We save the realm through crookedness,
Lord, make it right!

We must, O Father, must succeed:
"This is Thy cause,
O! help us in our hour of need,
The pockets of the rich to bleed,
That we may vindicate our creed,
And make Thy laws.

But if the people should decide
Against our case,
Let naught of evil me betide,
Let me find favor with the other side
And get a place.

Then I visited Dr. C. E. Munroe, the great census expert, famed as well for his knowledge of explosives, and we lunched at the Cosmos Club, where I found Fearar of State College, Pa., and Bigelow of the National Cannery Association who was good enough next morning to show me what good work he had accomplished at his new task.

My good host had placed his auto and driver at my disposal and we drove to the Bureau of Standards where Dr. Hillebrand, famed for exact analytical work, showed me through his new laboratory.

From there I visited my friend Swavelly of the Army and Navy School, a graduate of Lafayette College and an active and influential alumnus. During the day I made a visit to the Bureau of Chemistry of the Department of Agriculture and saw my friend Patterson at the meeting of the official Agricultural Chemists in session at the Willard. This was rapid work for two days but I had far to go. That night I bade Washington adieu and started for Charlottesville, Va., seat of its famous university. Here I was met by Dunnington, a young man when we last met, now talking of retiring. We visited Dr. Mallett's laboratory together—still as he left it—and talked about his great work. Dunnington had nothing to say about his own work. It was all Mallett. What a beautiful legacy is a loving memory like this! Dunnington, too, is building a new laboratory. It was here that Edgar Allan Poe and Woodrow Wilson and Richard K. Meade were students. In the distance Monticello could be seen.

In the afternoon I left for Staunton, which Virginians pronounce Staanton, on my way to Lexington, the seat of Washington and Lee University. After the civil war Robert Edward Lee, the greatest general the war produced, became president of the university which Washington had founded. Here he died and lies buried in a beautiful mausoleum with his wife and other members of his family. His study has not been touched since his death. If I had been a student here I should have been very proud of my alma mater. I was welcomed by my old friend, James Lewis Howe, famous for his work on the platinum metals and for his annual reviews of the progress of chemistry. Next morning I talked to the chemical students and met the bright young members of the teaching force.

In the afternoon we visited the Virginia Military Institute and met the professors of chemistry. It was here that Stonewall Jackson taught when the war broke out. Here he enlisted the first company of his famous foot cavalry, and here he is buried. Lexington should be proud of her great dead. Lexington is very proud of the beautiful Doremus Gymnasium and of the way in which the money for it was given.

It seems that Mr. and Mrs. Doremus visited many

colleges and finally decided that Washington and Lee was the most deserving. These visits were unannounced and the gift of \$2,000,000 was entirely unexpected. "Just think," said one of the professors, "what a reception he would have had had we known."

From Lexington a business call sent me back to Richmond, which I had not visited for many years. In the lobby of the Jefferson a Confederate veteran was selling Confederate money and Indian arrow heads. Richmond is a fine city, and appears to be growing rapidly. The chief occupation of the authorities is to find some new way of levying taxes. Even the capital of the merchants is to be taxed. I saw Dr. Carpenter, grown old in the service of the Virginia Carolina Chemical Company, and Dr. Wightman, the bright and active young professor of chemistry at Richmond College, who takes the place of Dr. Bingham, now my colleague at Lafayette.

From Richmond I journeyed to Chapel Hill, N. C., to visit my old friend, Dr. F. P. Venable. When I first knew him, Dr. Venable, who is the son of a former professor of mathematics at the University of Virginia, was professor of chemistry at Chapel Hill; then the trustees made him president. For fifteen years he bore this heavy burden and built fourteen buildings; then he asked to be allowed to go back to his first love. To mark their appreciation of his services the trustees created the Francis P. Venable Professorship of Chemistry and made him the incumbent for life.

Now he has begun life anew, and with Dr. Bell, a graduate of Dr. Lash Miller of Toronto, has undertaken to redetermine the atomic weight of zirconium.

North Carolina is a sort of chemical slop jar. In variety of minerals she is not to be excelled on the face of the earth. Zircon is one of these, and the atomic weight of zirconium has never been satisfactorily determined. Venable took me to his laboratory and showed me how he made zirconium chloride, how he had one by one overcome the innumerable difficulties until he now felt sure of ultimate success. I rejoiced with him, and told him what I had been doing. In the evening Dr. Herty came over to see me. Herty is president of the American Chemical Society and is to edit the "Journal of Industrial and Engineering Chemistry." In my further journey through the Southland I heard much of the Herty turpentine cup. Turpentine is a great industry in the South and Herty has done good work there.

Next day was Sunday, and we went to hear a sermon by Mr. Moss in the Presbyterian Church. It was a unique sermon—I never heard one like it—full of real meat. In the wall back of the pulpit were four marble tablets. One of these read as follows:

In memory of
Elisha Mitchell, D.D.

Born in Connecticut 1793,

Died on Black Mountain, N. C., 1857.

Professor of Mathematics and of Chemistry U. N. C.
1817-1857.

Ordained minister by Orange-Presbytery 1821.

Stated supply of this church for many years.

One of the builders of this house 1849.

After service we strolled around the town and admired the fine old houses set back from the streets and the beautiful gardens. The atmosphere reminded me of Oxford—there was the air of friendliness and genial ease though not quite so straight-laced as the Oxford I last saw.

Some time since, talking with the successful young sculptor Harry Raul, I said to him, "Why must we forever continue to reproduce in our architecture the Greek acanthus leaf, the egg and dart and the walls of Troy? Why not have an architecture of our own

in which the Indian corn, the wheat, the strawberry, mullein, cotton plant, the cypress and the poplar play a part?" Here I found the answer to my query in the law building, in which this idea had been carried out with happy effect. It is worthy of further elaboration. Why not have an architecture of our own and discard our slavish following of Greek and Goth?

In the absence of her mother, Miss Frances Venable presided over the dinner, and Drs. Wheeler and Bell were also guests. We spent the afternoon telling stories. F. P. is a famous raconteur. His darky stories are especially good. Dr. Wilson, librarian, who dropped in during the evening, reminded us of the darky who said apollinaris tasted like your foot's asleep.

Next morning I rode my auto to Durham and then by train to Winston-Salem, where I found two of my old students, J. L. Ludlow, a prosperous civil engineer, and Robert A. Rice, business manager of Salem College. Ludlow is buying spent pyrites from the sulphuric acid companies. It contains 2 per cent sulphur. He roasts it to a content of 0.05 per cent and at the same time clinkers it and sells the clinker to the iron blast furnaces. My two hours' stop here was soon at an end, and I went back to Greensboro on the way to Atlanta, my next stop. On the way to Greensboro we passed a station called Terra Cotta, where large stacks of the finished product show that the station was properly named. I found everywhere through the South evidences like this of an industrial awakening. Those who think the South still sleeps have not been abroad.

My visit to the Georgia School of Technology at Atlanta was a very pleasant one. I was very kindly treated, and although my visit was brief and made in a pouring rain it was very enjoyable. That evening I dined with Professor Daniel, who has done good work on the hydrogenation of oils; after dinner we went to the movies and talked shop instead of watching the pictures.

I reached New Orleans at 11 p. m. and went to the Grunewald, where, to my great surprise, I found my old friend Dr. A. L. Metz, chief of the chemical force of Tulane University, waiting to receive and welcome me.

Next day was Thanksgiving. In the morning I called up my old student G. G. Earl, chief engineer of the New Orleans Water Sewage and Drainage Commission. Mr. Earl drove me to one of the six pumping stations for lifting the sewage and drainage into Lake Pontchartrain. We saw two of the monster pumps designed and built under his direction capable of lifting 36,000 cu. ft. per minute. It certainly was a great pleasure to see what good work our graduate is doing.

At noon, with the chemical faculty of Tulane, I was Dr. Metz's guest at the Louisiana restaurant, after which we adjourned to his home, where we spent the afternoon and evening.

Next day, at Professor Williamson's invitation, I talked to the students in chemical engineering and aired my peculiar views on teaching. During that and the following days I visited the sugar plantation of Edward Godchaux at Reside, La., where I saw cane sugar made at the rate of 2000 tons daily, to the plant of the International Distilling Company at New Orleans, where cologne spirits and gin are made from black strap molasses, and two experimental plants, where potash is being recovered from the slop.

On my way home I stopped at Auburn, Ala., to see Dr. B. B. Ross, and we spent part of Sunday in a visit to Tuskegee, where John Washington kindly showed us over the interesting experiment. Another stop was made at Copperhill, Tenn., to see a new nitric acid

plant with twenty-one Hart condensers just installed with all the modern improvements. It was very interesting to see how my modest experiment of 1891 had expanded in the course of time into a large industry.

Easton, Pa.

Coming Meetings and Events

Society of Chemical Industry, New York Section, Perkin Medal Award, New York, Jan. 19, 1917.

Joint meeting of New York Section of American Electrochemical Society, American Chemical Society and Society of Chemical Industry, Rumford Hall, Chemists' Club, New York, Feb. 9, 1917.

American Institute of Mining Engineers, annual meeting, New York, Feb. 19-22, 1917.

Western Metallurgical Field

Ferro-Alloys

A 200-kw. electric furnace is being installed at Utah Junction, near Denver, for the production primarily of ferro-tungsten. The new company will operate under the name of the Ferro-Alloy Co. The contract for the plant has been let and it is hoped that operations will begin in 90 days. If the production and sale of the ferro-tungsten justifies it, other ferro-alloys will be manufactured. These are ferro-molybdenum, ferro-vanadium, ferro-manganese, ferro-uranium and ferro-silicon.

Case of the Government Against Trona Co.

The case of the government against the California Trona Company which has been trying to extract potash from Searles Lake was called on Nov. 27, and was continued pending a final agreement on stipulation so that the case will probably come up in a short time again. The government, in order to avoid a long drawn out legal battle, is endeavoring to put the case up to the Department of the Interior on the basis of a stipulation of facts.

The Trona Corporation has applied for patents in this case covering four 28-acre locations, furnishing a test case. An examination was made and charges preferred against the application, alleging:

First, the form and character of the deposit was not such as to be subject to location under placer mining laws.

Second, the application of the California Trona Company was not made for its own use and benefit, but for the use and benefit of a foreign corporation, thus making the application subject to disqualification.

The endeavor now in getting a stipulation of facts is to get a statement as to who owns the stock of the California Trona Corporation. It is known to be controlled by English interests. The procedure at present is to get statements on both sides and come to an agreement to prevent a legal battle.

The Trona Company has about completed a large plant at San Pedro (Los Angeles) and the machinery evaporators, centrifugals, etc., have been installed. The Searles Lake plant at Trona has been modified to a great extent, and much of the apparatus is believed to have been scrapped. As far as is known no production of potash has been made as yet by the Trona Company.

The following facts as to the plants at Trona and San Pedro are given in the *Mining and Oil Bulletin* for December of the Los Angeles Chamber of Mines and Oil.

The company's plant at Trona, Searles Lake, San Bernardino County, comprises a battery of 2000 hp. Bab-

cock & Wilcox boilers, housed in a steel and reinforced concrete building with a vertical flue of steel and concrete which is a monument to the designing and constructing engineers. This chimney is 150 ft. in height, and 9 ft. in diameter in the clear at the top. The evaporating building is 109 ft. high, 200 ft. long and 70 ft. wide, also constructed of steel and concrete. In addition a building 600 by 90 ft. houses the machinery for the production of potash salts and borax. The plant also includes a reinforced concrete spray pond for cooling the water used for the condensation of vapors; a 10,000 barrel oil tank; two 500,000 gal. steel tanks for brine, and several other tanks of 10,000 gal. each. The offices and laboratory are in a two-story reinforced concrete building. F. O. Engstrum Company, with offices at Fifth and Seaton Streets, Los Angeles, secured the contracts for the general construction work; all tanks used were furnished by the Llewellyn Iron Works, of Los Angeles and Torrance; steel and machinery were purchased from eastern dealers.

The camp equipment is modern in every detail, and comfortable bungalows are provided for the employees. A 32-mile standard gauge railroad has been completed, operating between Searles, a station on the Southern Pacific, and the company's plant at Trona. The brine is treated at Trona by evaporation and the concentrated product is to be shipped to the refinery at San Pedro.

When completed, the refinery at San Pedro which is not far from Point Fermin, will have a capacity of 200 tons of potash per day, and the output will also include a daily production of sixty or more tons of borax. Later the company will put on the market sodium carbonate, sulphate and chloride, and intends to erect additions to the plant for the manufacture of such potassium or sodium salts as the market may require.

The power plant at San Pedro contains 1000 hp. Babcock & Wilcox boilers, housed in a steel and reinforced concrete building, with a chimney of the same dimensions as that at Trona. The principal factory building is 86 ft. high, 200 ft. long and 80 ft. wide. The office building houses a modern laboratory, drafting and engineering departments. A warehouse 100 by 300 ft. will soon be constructed, also other necessary buildings with machinery for the preparation and sacking of the company's products. It is expected that the refinery will be operating before Jan. 1, 1917. The plant at Trona is, of course, now in operation. Plans are now being made to increase the size and output of both plants.

Company Reports

The Annual Report of the Vindicator Consolidated Gold Mining Co. for the year 1915 gives as one of the main features for this year the buying of the Golden Cycle Mining Company's property by the Vindicator Company. The latter adjoins the property of the Vindicator and consists of 43.5 acres. This purchase raises the total acreage of the Vindicator from 86 to 130 acres. The various departments of the two properties were consolidated.

In October, 1914, the Vindicator concentrating mill was put into operation, but did not run at full capacity until the first part of 1915. This mill was designed to handle the reject from the ore house and produce a shipping product from material which otherwise would have gone to waste. During the year the mill has handled an average daily tonnage of 250 tons in one shift of eight hours. The average ratio of concentration was 11 to 1. The average percentage of recovery was 55 per cent on an ore running \$2 per ton. The milling costs were only \$0.20 per ton. A complete return for the value expended was shown after only twelve months' operation.

Much experimenting has been done on the low-grade ore on the dumps averaging \$2 per ton or better, and on the low-grade ore in the mines and in the filled stopes. The engineers of the company, after thorough investigation, have recommended the remodeling of the shut-down mill at the Golden Cycle shaft. The flotation process will be used, and the mill is supposed to handle the rejects from the Golden Cycle ore-house and at the same time serve as an experimental station for the ores from all shafts. The capacity of the mill will be 300 tons daily and the cost of changing will be low. A 90 per cent recovery from material running \$1 per ton is expected. If this mill works out satisfactorily, after testing all the ores of the property, a modern flotation mill will be erected of not less than a thousand tons daily capacity. Such a mill will cost in the neighborhood of \$200,000, where a cyaniding mill of the same capacity would involve an expenditure of \$750,000.

During the twelve months' operation of the Vindicator and the ten months during which the Golden Cycle has been producing, there have been mined 218,487 tons of crude ore, which produced 125,397 tons of shipping ore averaging \$23.73 per ton. The gross value of the company's shipments amounted to \$2,164,668.92 and after deducting treatment charges and freight gave net receipts of \$1,718,022.21. Lessees over the same period of time shipped 49,188 tons of ore averaging \$16.57 per ton in gold. The gross value of this ore was \$815,182.59 and the net receipts amounted to \$546,363.55. The royalties received by the company from the lessees amounted to \$251,624.09.

The recovery of gross contents was 94 per cent of gold and 90.9 per cent of silver, a decrease of 1 per cent gold and 0.3 per cent silver. The value recovery based on net smelter returns shows 90.3 per cent against 89 per cent for the previous year, or a gain of 1.3 per cent. This is the highest net recovery in the history of the mill. The comparison of these last figures, coupled with the cost of operation, shows the efficiency of the mill. Had the supplies been normal in value an additional reduction of 35 cents per ton could have been made. The increased cost of chemicals is shown in the table.

The total cost to mine and mill the ore and market the products was \$7.78 per ton. The metal losses in milling and refining was equal to \$1.11 per ton. The profit per ton was \$4.77. The average gross value of the ore milled was \$13.66.

The Chicago Section of the American Institute of Mining Engineers held a dinner meeting at the Chicago Engineers' Club on Friday, Dec. 22. Mr. Alonzo G. Kenyon of the Powdered Coal Engineering and Equipment Co. spoke on "Burning Powdered Coal," and Prof. Harry B. Pulsifer of the Armour Institute of Technology spoke on "Metallurgical Plants About Chicago."

326th Meeting of the Colorado Scientific Society.—This meeting was held on Dec. 2 at the Colorado State Museum. Two papers were presented by Richard C. Hills, the first being "Some Rare Mineral Occurrences" and the second was entitled, "A Denver Made Spintharoscope for Counting the Helium Atoms Given Off by Radio-active Preparations."

The Perkin Medal for 1917 will be formally presented to Dr. E. Twitchell at the joint meeting of the New York Sections of the Society of Chemical Industry, American Chemical Society and American Electrochemical Society in the Chemists' Building, New York, on the evening of Jan. 19, 1917.

The Future of the Iron Blast Furnace

By J. E. Johnson, Jr.

That iron is the very basis of our industrial civilization will be admitted by the thoughtful, and many of our greatest supplies of iron ore are being rapidly depleted because of the increased per capita consumption of iron the world over, an increase which is destined to be greater in the future when the races in Asia and Africa increase their consumption of iron. Therefore, the question of a supply for future generations is one vital to the race and is worthy of some consideration here, in view of the fact that the changes in conditions which must come about will affect the economics, and through them the technology of the blast furnace. These conditions of increasing consumption and decreasing reserves have often in the past, particularly about the beginning of this century, been used to create a scare, on the ground that our supplies of usable ore were being so rapidly depleted that their exhaustion would occur within two or three generations. This is a point of view which seems to me preposterous, even leaving out of account the fact that the estimates of the world's iron ore resources, which were used in reaching this conclusion, were subsequently shown to be entirely inadequate. But the corrections which have since been made push into the future, only by a few brief centuries at most, the time at which the exhaustion of these reserves may be expected. It is then not here that our fundamental ground for optimism must be found, but in the fact that as we lower the percentage of iron in the rock, which we agree to call "ore," the quantity of such ore increases at a rate out of all proportion to the decrease in iron content.

In considering the decline in iron content, especially as to the rich ores, we must remember that as there are two oxides of iron containing in the chemically pure conditions different quantities of iron, we must consider them separately. Magnetite Fe_3O_4 contains 72.4 per cent of iron, hematite Fe_2O_3 , 70 per cent.

There have been magnetites found containing over 70 per cent in iron. In one region, a deposit was found, historically famous for its size and purity combined, in which there were more than 60,000 tons of ore running 70 per cent and over, but this same district contained millions of tons of ore 60 per cent and better, tens of millions of ore of 50 per cent and better, and hundreds of millions of tons containing 30 per cent and better. This, being magnetic ore and free milling, is considered as commercially available ore to-day, and while the same thing is not true commercially of hematites, yet to assume that methods will not be found to concentrate these also is to insult the intelligence of posterity. If we were to drop down to rocks containing 20 per cent of iron, the increase would be still greater.

I believe that this whole matter could be handled accurately upon the basis of the probability curve, but I am not mathematician enough to do it, nor have I been able to obtain the assistance of a mathematician who could, but such tentative figures as I have, obtained from an authoritative source, indicate that for every million tons of iron ore from 60 to 65 per cent iron content there are 85,000,000 tons of 30 to 35 per cent, and the increase is even more rapid as we drop below this point.

It is obvious then that we shall never run out of iron-bearing material—we shall simply use leaner and leaner material as time goes on.

This process has already proceeded further than we realize, unless we stop to look up the records of the past. A good standard of comparison is the fact that

when my father made an examination of the famous Chapin mine in 1891, just a quarter of a century ago, he found them throwing 56 per cent material over the dump as "rock."

The direct result of further change in the same direction will be to increase the cost of pig iron for the reasons elaborated in earlier articles, and this fact must be frankly faced. But we have seen increases in price of pig iron many times greater than that which would result from reducing the iron in the ore from 55 to 30 per cent, but neither the consumption of iron nor civilization was checked by these conditions; if one took only the superficial view they would appear to have been accelerated, and it is, therefore, reasonable to assume that if this condition of high prices becomes chronic for industrial reasons, instead of being spasmodic for commercial reasons, civilization would scarcely feel the difference, especially as it is a change which will take place with exceeding deliberation.

A change, such as that indicated above, would increase our resources in ore to an extent which staggers the imagination, and there is no reason to doubt that the tendency to increased cost, due to the use of leaner ores, would be met by technical and industrial improvements which would minimize if they did not wipe out the increase.

The same thing has happened in other industries. Gold ore worth \$10 per ton was probably not commercial fifty years ago; to-day gold is being extracted at a profit from ores which contain values of only \$1 per ton. Similarly the copper ores of fifty years ago were rich. In the early days of Calumet & Hecla the ore ran 3 per cent in copper and sometimes 4 per cent. It was sweetened by huge masses of native copper of such great size that in those early days of little or no equipment great difficulties were encountered in cutting them small enough to be brought out of the mine. Copper in that day commanded a price of 20 to 30 cents a pound; to-day mines are extracting copper from ore containing $1\frac{1}{2}$ per cent and less of the metal, and they could sell it, if they wished, at 8 cents a pound.

If nature has been more generous to the iron industry and endowed it with extensive supplies of ore, capable of immediate use in the furnace without beneficiation, that is no sign that the iron industry and civilization with it will be extinguished by the exhaustion of these deposits, and the consequent necessity of descending to ores containing only a fraction as much metal.

Advances are to be expected along both industrial and technical lines. Much of the value of the high-grade ores of to-day is made up of two elements—a rarity value, namely, the royalty paid to the owner because of the exclusive ownership of existing deposits, and a transportation value due to the necessity of bringing these relatively rare rich ores to the point of consumption.

If the day ever comes when we drop down, for instance, to 30 per cent ores, the bodies of these are so vast that exclusive ownership will be almost impossible, and the royalty value will greatly decline or fade away, while, owing also to the relative numerousness of such bodies of material, the chances are that they will be found much closer to the points of consumption than the rich but rare bodies of to-day. This, then, will tend to reduce the transportation values of these ores, or at least will tend to offset the increased cost of transportation, due to the greater number of tons required per ton of iron.

On the technical side, improvements may reasonably be expected along four lines—mining, ore dressing, by-products, and the furnace itself.

Mining

Cheaper mining is to be expected because we shall be able to choose among the most favorably located of the great deposits of low-grade material, and for centuries probably nothing but open pit work will be done upon them, which will mean a minimum of cost.

Ore Dressing

In regard to ore dressing, the metallurgy of iron is far behind any other, partly because of nature's hitherto bountiful supply of ores directly available, and partly because the blast furnace, being a willing horse, has often been made to carry an unfair burden. Its proper task is the reduction of iron to the metallic state from its oxide; it has also often been made to serve as an ore dressing apparatus and separate the iron from the gangue as well, for the good commercial reason that it furnished the cheapest way to do it, if other conditions were right. Most of the science of ore dressing for the iron industry, therefore, lies in the future, and there, as far as this work is concerned, we must leave it, since it is impossible to foretell the lines of development which will follow, and they would be out of place here, if we knew them.

By-Products

It is only within the last ten or twelve years that we have been accustomed to consider the by-products from the furnace as having any value, but leaving aside for the present the question of the gas, we are coming to an increased realization of the importance of the slag in making cement. As concrete construction grows in relative importance to steel, as well as in an absolute importance, and as the quantity of slag per ton of iron increases, which it necessarily must from the use of leaner ores, we must look for a wider and wider application of this slag to the production of cement. We may even hope that the present method of manufacture, which theoretically at least seems very crude, will in time to come be improved, revolutionized perhaps, so that what one furnaceman has been accused of dreaming—tapping iron out of the iron notch and cement out of the cinder notch of the blast furnace—may almost come to pass.

If the cinder can be converted into cement with a profit which will only pay for handling the gangue of the ore and the limestone to flux it, the furnace of the future will obviously be relieved of a heavy part of its increased burden.

The Blast Furnace

Turning now to the furnace itself, whatever we say or suggest must be taken in the light of prophecy and subject to all the errors and discounts to which all prophecy is subject, because if there were means whereby we could increase the economy of the furnace when running on lean ores beyond the present possibilities, obviously it would not be a matter for the future, but would be in process of being done to-day.

Turning back to the article on commercial considerations, it is easy to believe that the furnace of the future will feel no particular pressure on account of fuel consumption until the latter has risen beyond the point at which the furnace gases will supply all the heat and power requirements of the associated steel mill, except, of course, at isolated merchant furnaces having no such market for their power. The question as to how we shall reduce the fuel consumption, when this point is reached, is the ultimate question which the industry must answer, and though it is a long way in the future for us, there are visible, even to-day, means whereby it may be done. Of course, the possibilities of hotter

blast and all the other lines along which present developments are progressing will have been pretty well exhausted by that time; we must look for a more radical solution.

This, in my judgment, is to be found in the modern industry of separating the oxygen from the nitrogen of the atmosphere by purely physical means, and using this instead of air to blow the furnaces of the future. This idea is not novel in the industry. Experiments were made in the direction of enriching the oxygen content of the blast in Belgium a year or two previous to the breaking out of the Great War, but no important results were obtained, or at least those published were unimportant because the degree of enrichment was too small to produce any marked change. Some American furnacemen have taken the ground that no gain was to be expected on theoretical or practical grounds. If that contention be correct, the fundamental principles of the blast furnace, as set forth in a former article of this serial are wrong, the explanations of known phenomena made on the basis of these principles are incorrect, and there is scarcely an article in the serial which can be accepted without the most drastic revision. If, on the other hand, the thermal principles set forth are correct, then we may proceed to show quantitatively the effect which oxygen in different proportions would have upon the thermal relations in the hearth and bosh of the furnace.

Fig. 1 is a diagram giving the quantities of hearth heat obtainable per pound of coke (counting 0.85 lb. of fixed carbon burned in the hearth) with dry air blast at 1000 deg. Fahr., and with a mixture of equal weights of oxygen and nitrogen at atmospheric temperature. This diagram shows that at low critical temperature there is but little advantage in the oxygen blast, but as the critical temperature rises the advantage increases from a few per cent to several hundred per cent.

FIG. 1.—HEARTH HEAT PER POUND OF COKE (COUNTING 85 PER CENT FIXED CARBON BURNED IN HEARTH) AT DIFFERENT CRITICAL TEMPERATURES WITH BLAST OF DRY AIR AT 1000 DEG. FAHR., AND WITH BLAST OF EQUAL WEIGHTS OF OXYGEN AND NITROGEN

The study of this diagram enables us to see what changes may be made in the thermal operation of the furnace by the use of oxygen blast.

There are many who will doubt the possibility of obtaining the supply of oxygen which would be required for such a use, but the process of separating air into its component oxygen and nitrogen on an industrial scale by distillation from liquid air is now in actual operation at Niagara Falls, separating many thousand cubic feet of air per hour.

Those who remember the ridiculous claims made for liquid air some eighteen years ago, and their subsequent utter collapse, are inclined to deny the commercial possibility of that operation, on theoretical grounds, but this is not correct. The theoretical power for effecting the separation, figured on the basis outlined by Ostwald, the great apostle of physical chemistry, amounts to only 1 hp. per 6 cu. ft. of oxygen produced per minute. A modern 500-ton blast furnace requires 45,000 cu. ft. of air or 9000 cu. ft. of oxygen per minute, which would require, on the theoretical basis, 1500 hp. for its production, as against the 2500 hp. now necessary to blow the furnace.

The best performance of any actual air separating operation to-day requires about seven times the theoretical amount of power, so we are still far from being able to replace existing methods on the power basis. Processes are under development, however, which promise to reduce this power requirement by one-half or two-thirds; in other words, we hope to produce oxygen at an efficiency of 50 per cent, based on theoretical power, and there is no fundamental reason why we should not do so. Even this, it will be said, is no improvement over present conditions, and on the power basis alone that would be true. But this question cannot be decided on the power basis alone, for two reasons:

1. The heat consumption of the blast under present blast furnace conditions is not limited to power alone.

2. The result in the furnace itself must be considered.

In regard to the first point, it must be remembered that blast must not only be compressed, but it must be heated, and this operation requires about four times the heat required to supply power for compression; then there is the heating equipment, which costs as much as the power plant, all of which would be saved by the use of oxygen. This brings us to the second point, the effect of oxygen in the furnace itself.

It will be seen that for the average condition, 2750 deg. critical temperature, the hearth heat with the ordinary hot blast is about 1800 B.t.u. per pound of coke, while with the 50 per cent oxygen blast, it is 2625 B.t.u.; in other words, we can raise the amount of hearth heat obtainable from a given amount of coke nearly 50 per cent by the use of a blast containing one-half oxygen. If the critical temperature be higher the advantage is still greater.

Let us remember that it has been shown in the article on thermal principles that the rapid increase in fuel consumption with leaner ores comes principally from the increased slag to be melted, and the volume of slag increases with enormous rapidity as the percentage of iron in the ore declines. The average Lake Superior ore of 52 per cent iron produces about half a ton of slag per ton of iron. Ore of 33 per cent iron and 38 per cent silica produces about $2\frac{1}{4}$ tons of slag, which at 0.4 of a ton of coke per ton of slag means an increase of 0.7 of a ton of coke. On the same basis, an ore containing about 25 per cent iron Fe, 43 per cent SiO_2 , and 15 per cent Al_2O_3 , would produce 5 tons of slag per ton of iron which, on the basis of 0.4 of a ton of coke, would demand an increase of almost 2 tons in the coke required to make a ton of iron, working under present conditions.

If the total coke per ton of iron became 3 tons with ordinary hot blast, on the basis of the hearth heat developed, it would drop back to 2 tons with half oxygen blast.

But we must consider the development of shaft heat as well as hearth heat. With lean ore and half oxygen blast, we should require more than under present conditions, for two reasons:

1. The larger quantity of slag forming materials to be heated to the critical temperature in the shaft.

2. The smaller quantity of nitrogen present to carry heat from the hearth up into the shaft.

But we have seen in discussing thermal principles that a reduction of the amount of fuel required to smelt a given weight of iron automatically increases the amount of heat available in the shaft, because a larger proportion of the CO present at the top of the bosh is oxidized to CO_2 by the oxygen of the ore, with a correspondingly greater development of shaft heat.

We have seen further that solution loss is one of the prime causes of insufficient shaft heat development, as well as of insufficient hearth heat development.

In order to eliminate this loss more or less completely, especially in the upper regions of the furnace, where the concentration of CO_2 and the solvent action are the greatest, I have suggested a furnace in which the fuel should be fed down through the center of the furnace, and for some distance down kept from contact with the ore, while the gas was made to travel the last portion of its journey through the ore alone, thereby eliminating its alternating contact with ore and fuel, the prime cause of solution loss with the present process.

This design is shown by Figs. 2 and 3. The water-cooled steel mantle with a fluted bottom is supported from the top of the furnace, its top is sealed and no escape of gas permitted therefrom. The fluting is intended to promote a quick and intimate mixture of the ore and fuel in the lower regions of the furnace.

It is hardly necessary to say that this scheme has never been tried, nor has the use of oxygen blast in any percentage calculated to produce revolutionary results. The whole idea must, therefore, be counted as a dream, for the present, but in considering the possibilities of the future, as we now are, it is well to remember that incredulity has discounted the wisdom of the race many times oftener than credulity, and allowing that the supply of oxygen can be obtained, which is a possibility now almost appearing within sight over the horizon, there is nothing in the principles of furnace operation, as we know them, to cast doubt upon the possibilities of such a design.

Objections will naturally occur to the thoughtful, but they are more apparent than real. Perhaps the first would be the difficulty of maintaining the furnace structure in the intense heat produced by the combustion of carbon in oxygen, but the answer to this is easy. We do not desire or intend to produce any higher temperature than we now have. We propose merely to generate more high temperature heat, and then give it enough more work to do to bring the temperature back to where it is to-day, always remembering that, in the broad sense, the temperature prevailing in any zone of combustion is proportional to the amount of heat developed, divided by the thermal capacity of the materials present.

Another objection will be that the reduced area available for the passage of the gas will not permit the furnace to be blown at any speed worthy of consideration. Here, again, appearances are in error, because a blast containing one-half oxygen has a total volume less than one-half that of air containing the same quantity of oxygen. If by the use of oxygen we reduce the fuel

consumption to two-thirds, the gas per ton of ore becomes approximately one-half what it would be with atmospheric blast under the same conditions, and this can, therefore, pass out through an area one-third as large.

On the other hand, such a process has some advantage over the existing furnace in other respects besides fuel consumption. First is the production as a by-

Of course, we do not know that the blast furnace, the oldest industrial apparatus still in the service of man, will survive the changes which the future is to bring. Other methods of smelting iron have been proposed, and while they have in the main failed, a careful study of the thermal principles will show that they need not necessarily fail on theoretical grounds; but if the blast furnace remains our best, or even our only servant for the conversion of nature's stores of iron to our use, it is evident that there are long strides in sight which it may take, and that when these are taken it will be

FIG. 2—PROPOSED DESIGN OF BLAST FURNACE FOR OXYGEN BLAST

FIG. 3—DETAILS OF FIG. 2

product of a large quantity of pure nitrogen, and it is reasonable to believe that this would, to a large extent, come into use for fixation purposes. Second, because the fuel does not require to be penetrated by the gas column, but should be made as impervious as possible to it; a part of the fuel could be charged as coal, not coke, and this would save a corresponding proportion of the coking cost, and the investment for ovens.

There are other advantages over the present process if we could make this dream true. Not the least, perhaps, would be the elimination of the stoves and the consumption of gas required to heat them. The furnace would not need to have so large a volume on account of the much smaller volume of gas passing through it and the correspondingly greater concentration of the latter in active components. The furnace gas would be richer on account of the elimination of the nitrogen, in spite of being more diluted with CO_2 .

possible for us to use commercially as ores what we should now dismiss as rock, and that the supply of raw material thereby placed at our disposal is so enormously enhanced that we can more easily foresee the failure of civilization from other causes than from the failure of its supply of iron and steel.

Fuel Oil Requirements of the Navy.—In his annual report to Congress, Secretary of the Navy, Daniels, points out that when the three-year program already authorized by Congress is completed the Navy will require 6,721,000 barrels of fuel oil annually during peace. All new ships are oil burners and the navy has taken steps to acquire oil lands to be held in reserve. This future supply is threatened by legislation which would benefit others and the Secretary makes a plea for the upholding of public interest against private ownership.

Supreme Court Decision in Hyde Flotation Suit

The complete text of the decision of the Supreme Court, written by Judge Clarke, in the suit of Minerals Separation Ltd. and Minerals Separation American Syndicate, Ltd. versus James M. Hyde is as follows:

In this suit the complainants, the first named as the owner and the other as general licensee, claim an infringement of the United States letters patent No. 835,120, issued on the 6th day of November, 1906, to Henry Livingstone Sulman, Hugh Fitzalis Kirkpatrick-Picard, and John Ballot. The usual injunction, accounting and damages are prayed for. The District Court sustained the patent as to claims numbered 1, 2, 3, 5, 6, 7, 9, 10, 11, and 12; found that the defendant had infringed each of these claims, and granted the prayer of the petition. The Circuit Court of Appeals for the Ninth Circuit reversed the decree of the District Court and remanded the case with instructions to dismiss the bill. The case is here on writ of certiorari to review that decision.

As stated in the specification, the claimed discovery of the patent in the suit relates "to improvements in the process for the concentration of ores, the object being to separate metalliferous matter from gangue by means of oils, fatty acids, or other substances which have a preferential affinity for such metalliferous matter over gangue."

The answer denies all of the allegations of the bill and avers that in twenty-five designated United States and five British patents the process described in suit was "fully and clearly described and claimed," and it also avers that the claimed discovery was invented, known and used by many persons long prior to the time when the application was made for the patent in suit. Notwithstanding this elaboration of denial counsel for the defendant in the summarized conclusion to their brief rely upon only five of the many patents referred to as showing that the patent in suit was anticipated and is therefore invalid for want of novelty and invention, viz.: Everson (1886), Froment (Italy, 1902; Great Britain, 1903), Glagner (1903), Schwartz (applied for April 19, 1905, issued Dec. 19, 1905), and Kirby (applied for Oct. 17, 1903, issued Dec. 18, 1906). And the defendant, a man obviously experienced in the subject, says that, in his opinion, the whole basis of flotation concentration was disclosed in the Everson United States patent No. 348,157 and in the Froment British patent.

It is clear that in the prior art, as it is developed in this record, it was well known that oil and oily substances had a selective affinity or attraction for, and would unite mechanically with, the minute particles of metal and metallic compounds found in crushed or powdered ores, but would not so unite with the quartz, or rocky non-metallic material, called "gangue." Haynes' British patent (1860), and United States patents, Everson (1885), Bobson (1897) and Elmore (1901). It was also well known that this selective property of oils and oily substances was increased when applied to some ores by the addition of a small amount of acid to the ore and water used in process of concentration. United States patents Everson (1885), Elmore (1901) and Cattermole (1904).

Prior to the date of the patent in suit a number of patents had been granted in this and other countries for processes aiming to make practical use of this property of oil and of oil mixed with acid in the treatment of ores, all of which, speaking broadly, consisted in mixing finely crushed or powdered ore with water and oil, sometimes with acid added, and then in variously treating the mass—"the pulp"—thus formed so as to separate the oil, when it becomes impregnated or loaded with the metal and metal-bearing particles, from the valueless gangue. From the resulting concentrate the metals were recovered in various ways.

The processes of this general character described in the prior patents may be roughly divided into two classes. The process in the patents of the first class is called in the record the "Surface Flotation Process" and it depends for its usefulness on the oil used being sufficient to collect and hold in mechanical suspension of the small particles of metal and metalliferous compounds and by its buoyancy to carry them to the surface of the mixture of ore, water and oil, thus making it possible, by methods familiar to persons skilled in the art, to float off the concentrate thus obtained into any desired receptacle. The waste material, or gangue, not being affected by the oil and being heavier than water sinks to the bottom of the containing vessel and may be disposed of as desired.

The process of the other class, called in the record the "Metal Sinking Process," reverses the action of the Surface

Flotation Process and is illustrated by the Cattermole U. S. patent, No. 777,273, in which oil is used to the extent of 4 per cent to 6 per cent to 10 per cent of the weight of the metalliferous mineral matter, depending on the character of the ore, for the purpose of agglomerating the oil-coated concentrate into granules heavier than water, so that they will sink to the bottom of the containing vessel, permitting the gangue to be carried away by an upward flowing stream of water.

The process of the patent in suit, as described and practised, consists in the use of an amount of oil which is "critical" and minute as compared with the amount used in prior processes "amounting to a fraction of 1 per cent of the ore," and in so impregnating with air the mass of ore and water used, by agitation—"by beating the air into the mass"—as to cause to rise to the surface of the mass, or pulp, a froth, peculiarly coherent and persistent in character, which is composed of air bubbles with only a trace of oil in them, which carry in mechanical suspension a very high percentage of the metal and metalliferous particles of ore which were contained in the mass of crushed ore subjected to treatment. This froth can be removed and the metal recovered by processes with which the patent is not concerned.

It is obvious that the process of the patent in suit, as we have described it, is not of the Metal Sinking class, and while it may, in terms, be described as a Surface Flotation Process, yet it differs so essentially from all prior processes in its character, in its simplicity of operation and in the resulting concentrate, that we are persuaded that it constitutes a new and patentable discovery.

The prior processes which we have described required the use of so much oil that they were too expensive to be used on lean ores, to which they were intended to have their chief application, and the efforts of investigators for several years prior to the discovery of the process in suit had been directed to the search for a means or method of reducing the amount of oil used, and it is clear from the record that approach was being made, slowly, but more and more nearly to the result which was reached by the patentees of the process in suit in March, 1905. The Froment Great Britain patent (1903) and the Kirby United States patent (applied for in 1903 and granted in 1906) are especially suggestive of the advance which was being made toward the desired result, but the Froment process was little more than a laboratory experiment and has never proved of value in practice, and the Kirby process, though approaching in some respects more nearly to the end attained by the process of the patent in suit, found its preferred application in the use of an amount of oil solution equal to one-fourth to three-fourths in weight of the ore treated, which was prohibitive in cost.

Into this field of investigation at this stage of its development came the patentees of the patent in suit. They were experienced metallurgists of London, of inventive genius and with financial resources, and they entered upon an investigation of the processes of oil concentration of ores which was continued through several years, and consisted of a very extended series of experiments in which the quantities of oil, of water and of acid used and the extent and character of the agitation of the mass under treatment resorted to, were varied to an almost unparalleled extent as to each factor and the results were carefully tabulated and interpreted. It was while pursuing a comprehensive investigation of this character, having, as the evidence shows, the special purpose in mind at the time to trace the effect on the results of the process of a reduction to the vanishing point of the quantity of oil used, that the discovery embodied in the patent in suit was made.

The experimenters were working on the Cattermole "Metal Sinking Process" as a basis when it was discovered that the granulation on which the process depended practically ceased when the oleic acid (oil) was reduced to about 5 per cent "on the ore." It was observed, however, that, as the amount of oleic acid was further reduced and the granulation diminished, there was an increase in the amount of "float froth," which collected on the surface of the mass and that the production of this froth reached its maximum when about 1 per cent or slightly less "on the ore" of oleic acid was used. This froth, on collection, was found to consist of air bubbles modified by the presence of the minute amount of oil used and holding in mechanical suspension between 70 per cent and 80 per cent of the total mineral content of the mass treated. It was promptly recognized by the patentees that this froth was not due to the liberation of gas in the mass treated by the action of the dilute acid used, and its formation was at once attributed in large part to the presence of the air introduced into the mixture by the agitation which had been resorted to to mix the oil with the particles of crushed ore, which air, in bubbles, attached itself to the mineral particles, slightly coated as they

were with what was necessarily an infinitesimal amount of oil, and floated them to the surface. The extent of the agitation of the mass had been increased as the experiments proceeded until the "series of Gabbett mixers, fitted with the usual baffles, were speeded at from 1000 to 1100 revolutions per minute."

A careful consideration of the record in this case convinces us that the facts with respect to the process of the patent in suit are not overstated by the plaintiffs' witness, Adolph Liebmann, an expert of learning and experience, when he says in substance:

"The present invention differs essentially from all previous results. It is true that oil is one of the substances, but it is used in quantities much smaller than was ever heard of, and it produces a result never obtained before. The minerals are obtained in a froth of a peculiar character, consisting of air bubbles which in their covering film have the minerals embedded in such manner that they form a complete surface all over the bubbles. A remarkable fact with regard to this froth is that, although the very light and easily destructible air bubbles are covered with a heavy mineral, yet the froth is stable and utterly different from any froth known before, being so permanent in character that I have personally seen it stand for twenty-four hours without any change having taken place. The simplicity of the operation, as compared with the prior attempts, is startling. All that has to be done is to add a minute quantity of oil to the pulp to which acid may or may not be added, agitate for from two and one-half to ten minutes and then after a few seconds collect from the surface the froth which will contain a large percentage of the minerals present in the ore."

It is not necessary for us to go into a detailed examination of the process in suit to distinguish it from the processes of the patents relied on as anticipations, convinced as we are that the small amount of oil used makes it impossible that the lifting force which separates the metallic particles of the pulp from the other substances of it is not to be found principally in the buoyancy of the oil used, as was the case in prior processes, but that this force is to be found chiefly in the buoyancy of the air bubbles introduced into the mixture by an agitation greater than and different from that which had been resorted to before and that this advance on the prior art and the resulting froth concentrate so different from the product of other processes make of it a patentable discovery as new and original as it has proved useful and economical.

It results without more discussion, that we fully agree with the decision of the House of Lords, arrived at upon a different record and with different witnesses, but when dealing with the equivalent of the patent in suit, in *Minerals Separation, Limited, v. British Air Concentration Syndicate, Limited*, 27 R. P. C. 33. In this decision Lord Shaw, speaking for the court and distinguishing the process there in suit especially from the Elmore oil flotation process which had gone before but which was typical of the then prior art said: "They (the patentees of the Agitation Froth Process of the patent in suit) are not promoting a method of separation which had before been described, but they are engaged upon a new method of separation. Instead of relying upon the lesser specific gravity of oil in bulk they rely upon the production of a froth by means of an agitation which not only assists the process of the minute quantities of oil reaching the minute particles of metal, but forms a multitude of air cells, the buoyancy of which air cells, forming around single particles of the metal, floats them to the surface of the liquid."

And Lord Atkinson said: "In the process this mysterious affinity of oil for the metallic particles of the ore is availed of, yet the oil is used in such relatively infinitesimal quantities that the metallic particles are only coated with a thin film of it, and the lifting force is found not in the natural buoyancy of the mass of added oil, but in the buoyancy of air bubbles, which, introduced into the mixture by the more or less violent agitation of it, envelop or become attached to, the thinly oiled metallic particles, and raise them to the surface, where they are maintained by what is styled the surface tension of the water."

The record shows not only that the process in suit was promptly considered by the patentees as an original and important discovery, but that it was immediately generally accepted as so great an advance over any process known before that, without puffing or other business exploitation, it promptly came into extensive use for the concentration of ores in most, if not all, of the principal mining countries of the world, notably in the United States, Australia, Sweden, Chile and Cuba, and that, because of its economy and simplicity, it has largely replaced all earlier processes. This, of itself, is persuasive evidence of that invention which it is the purpose of the patent laws to reward and protect.

Diamond Rubber Co. v. Consolidated Tire Co., 220 U. S. 428; *Carnegie Steel Co. v. Cambria Iron Co.*, 185 U. S. 403, 429, 430; *The Barbed Wire Patent*, 143 U. S. 275; *Smith v. Good-year Dental Vulcanite Co.*, 93 U. S. 486.

The claim that the patentees of the patent in suit are not the original discoverers of the process patented because an employee of theirs happened to make the analysis and observations which resulted immediately in the discovery, cannot be allowed. The record shows very clearly that the patentee planned the experiments in progress when the discovery was made; that they directed the investigations day by day, conducting them in large part personally and that they interpreted the results. *Agawam Company v. Jordan*, 7 Wall, 583-603, rules this claim against the defendant.

Equally untenable is the claim that the patent is invalid for the reason that the evidence shows that when different ores are treated, preliminary tests must be made to determine the amount of oil and the extent of agitation necessary in order to obtain the best results. Such variation of treatment must be within the scope of the claims, and the certainty which the law requires in patents is not greater than is reasonable, having regard to their subject matter. The composition of ores varies infinitely, each one presenting its special problem, and it is obviously impossible to specify in a patent the precise treatment which would be most successful and economical in each case. The process is one dealing with a large class of substances and the range of treatment within the terms of the claims, while leaving something to the skill of persons applying the invention, is clearly sufficiently definite to guide those skilled in the art to its successful application, as the evidence abundantly shows. This satisfies the law. *Mowry v. Whitney*, 14 Wall. 620; *Ives v. Hamilton*, 92 U. S. 426, and *Carnegie Steel Co. v. Cambria Iron Co.*, 185 U. S. 403, 436, 437.

The evidence of infringement is clear.

While we thus find in favor of the validity of the patent, we cannot agree with the District Court in regarding it valid as to all of the claims in suit. As we have pointed out in this opinion, there were many investigators at work in this field to which the process in suit relates when the patentees came into it, and it was while engaged in study of prior kindred processes that their discovery was made. While the evidence in the case makes it clear that they discovered the final step which converted experiment into solution, "turned failure into success" (*The Barbed Wire Patent*, 143 U. S. 275), yet the investigations preceding were so informing that this final step was not a long one and the patent must be confined to the results obtained by the use of oil within the proportions often described in the testimony and in the claims of the patent as "critical proportions" "amounting to a fraction of 1 per cent of the ore," and therefore the decree of this court will be that the patent is valid as to claims Nos. 1, 2, 3, 5, 6, 7 and 12, and that the defendant infringed these claims, but that it is invalid as to claims 9, 10 and 11. Claims No. 4, 8 and 13 were not considered in the decree of the two lower courts and are not in issue in this proceeding.

The decision of the Circuit Court of Appeals will be reversed, and the decision of the District Court, modified to conform to the conclusions expressed in this opinion, will be affirmed.

Bureau of Standards to Study Refractories.—The Bureau of Standards has begun an investigation of clay refractories in co-operation with the American Refractories Manufacturers' Association and the American Gas Institute. The bureau also has begun preliminary work on another investigation dealing with a phase of the same industry, using a dolomite in certain metallurgical furnaces as a refractory. Usually the burned dolomite is placed directly in position in the furnace with tar or some other combustible material as a binder. Where the lining was of such a nature that it had to be made of brick, magnesite brick was used. The price of magnesite brick, however, has advanced to such a degree that the use of this material has become almost prohibitive. It has been suggested at various times that dolomite might be burned in such a manner, or with the addition of such impurities that the lime present in it would not slake, except after an extended period, making it possible to produce a brick of this material which would replace the magnesite brick. The bureau by its investigation will determine the possibility of producing such a burned dolomite.

Current Efficiency in Copper Refining

By Lawrence Addicks

Current efficiency in an electrolytic operation is the ratio between the weight of product obtained per ampere hour and that called for by Faraday's law, for the current used in the desired reaction. It has therefore much to do with the cost of operations, but in this connection it must be considered jointly with the voltage factor; for example, the series system in copper refining operates at a lower current efficiency than the multiple and yet yields a greater weight of cathode per kilowatt-hour expended in the cell. For any given case, however, it is desirable to obtain as high a current efficiency as may be consistent with the cost of securing it, and it is our purpose to examine this question in its bearing to the multiple system of electrolytic copper refining.

The percentage which we obtain by dividing the weight in grams of cathode per ampere hour by 1.186 is less than 100 because part of the current performs no electrolytic operation on account of leakage or short circuits between electrodes, part is involved in reactions not desired and a portion of the cathode itself is redissolved chemically. It is even possible to obtain apparent efficiencies above 100 per cent under certain conditions.

In order to secure an exact correspondence with Faraday's law various niceties of operation must be observed and a great deal of study in this direction has been applied by those interested in voltmeter measurements. It is quite possible, however, with care and dismissal of questions of labor cost, to obtain a working efficiency on a large scale of 99 per cent. Commercially it is found, however, that about 92 per cent is as high a figure as it is advisable to insist upon and at some plants 90 per cent or even 88 per cent is considered satisfactory. Current density has a direct bearing on the problem in that a high density greatly increases the difficulty in preventing short circuits between the electrodes.

The various factors involved may be classified as follows:

A. Current leakage:

- a. To ground.
- b. Through electrolyte.
- c. Between electrodes.

B. Reaction:

- a. Deposition of impurities.
- b. Gassing.
- c. Valence.

C. Cathode shrinkage:

- a. Sulphatizing.
- b. Ferric salts.
- c. Nodules, etc.

A. Current Leakage

(a) *To Ground.*—The insulation resistance of the circuit from the ground may be determined by noting the reading of a high-resistance voltmeter when connected from either switch terminal on the live circuit to the ground by a simple application of Ohm's law. The current flowing through the voltmeter is obtained by dividing its reading by its known resistance; the total resistance in the leakage circuit is obtained by dividing the known line voltage by this current; the insulation resistance is found by subtracting the known voltmeter resistance.

It is evident that the resistance found in this way is a measure of the obstacles in the path of the current from the ground back through improper channels to

the other leg of the circuit, and that by opening the main circuit at predetermined points and taking repeated measurements a leakage map could be worked out. This, however, should not be necessary, as while the insulation resistance of an electrolytic circuit will always be low—a usual value is five ohms—the actual loss of effective current from this source is a minor matter in any plant where the foundation piers are properly capped with glass plates and tank leaks kept from resulting in sulphate crystals climbing around promiscuously.

If we assume that a circuit has a total resistance of five ohms from one side to the other through the ground and that the line voltage is 150, this leakage will be but 30 amp. If the main current is 10,000 amp. and the leakage uniformly distributed so that it robbed an average of but half the tanks, the percentage loss would be but 0.15 per cent.

(b) *Through Electrolyte.*—There are three ways of determining the loss of effective current due to improper shunt circuits through the circulation system: by direct measurement, by Ohm's law calculations and by Faraday's law calculations.

The direct method consists of placing carefully calibrated ammeters at various points in the circuit and comparing their readings, which would be identical except for losses under (a) and (b). Considerable care is required to avoid errors in measurement as thermoelectric effects may creep into the temporary shunt connections and magnetic errors, due to strong stray field, may distort the meter readings even when the instruments are protected by iron cases. An unprotected portable instrument may even be permanently thrown out of adjustment by exposure of its permanent magnets to the action of the stray field which exists within a couple of feet of a conductor carrying 10,000 amp.

Another method is to open the circuit in the center and note how many amperes are recorded by the powerhouse ammeter when full voltage is applied. This is not fair in that the voltage distribution throughout the circuit is not normal.

It will generally be found that the tanks at the far end of a circuit receive 3 or 4 per cent less than the switchboard current.

Ohm's law calculations may be made upon the liquid columns of electrolyte, as we know the resistance per cubic inch of the liquor, its physical dimensions and the voltages operating. Where the voltages are sufficiently low the lead pipe cannot act as a conductor, as when the current leaves it there must be sufficient voltage to decompose water. When such voltages occur sections of hard rubber or of rubber hose are employed to break the continuity of the metal path. It is also possible to take fall of potential readings along a lead pipe and figure the current flowing therein by Ohm's law and the specific resistance of hard lead.

Finally, we know that wherever the current enters the piping system it must deposit Faraday's equivalent of copper. This is of great practical assistance, as while it gives no information regarding the current flowing in the liquid itself, it does bring to daily attention any abnormal participation of the conduit system, and the accumulation of copper trees demands early attention to avoid stopping up the pipes.

The coating of lead sulphate which covers all tank linings and pipes exposed to the action of the electrolyte acts as an insulating paint of much value, as shown by the low efficiencies always obtained in starting up a new installation of bright tanks. A final insulating joint is usually effected where the electrolyte leaves a tank by allowing it to fall freely into the launder without a containing pipe for some inches.

Altogether ample means exist for measuring and controlling this source of loss.

(c) *Between Electrodes*.—The direct touching of anode and cathode is the most usual cause of poor efficiency. This condition can be brought about by the electrodes being carelessly spaced in the tank, by the curling of starting sheets, by falling of anode scrap, by omission of electrode insulators, by electrodes displaced sideways so as to touch the lead lining of the tank, by "treeing" of the cathode deposit, by the accumulation of an excessive quantity of slimes in the bottom of the tank or by the careless leaving of tools lying on top of the electrodes.

It is obvious that with the exception of "treeing" and falling anode scrap these causes may be removed in proportion to the amount of labor and inspection applied. Treeing involves the control of the cathode deposit by the choice of a suitable cathode age for the current density employed, adequate circulation of the electrolyte and the use of additional agents.

A cathode deposit starts as a fine frosting, and with a violent circulation this builds up with perfect smoothness. It is not possible to employ even a rapid circulation, however, on account of the consequent stirring up of anode slimes, and any mechanical scouring effect is therefore lost. On the other hand, the circulation must be maintained at a rate sufficient to supply copper ions at the cathode as fast as demanded by the current density, or other ions will act as carriers of the current and the deposit will become rough and non-adherent. Even under normal conditions fine needles soon spring out in crystal formation. The moment the cathode surface becomes roughened the parts nearest the anode offer the path of least resistance to the current and bad soon becomes worse.

The function of addition agents is first to round off these needles into blunt nodules, and second to change what is called "cocoa matting" structure to a hard compact deposit. Ordinary lubricating oil possesses some property which effects the first and minute quantities of glue the second.

The falling apart of scrap anodes results from incomplete refining of the blister copper in the anode furnace. As the condition causes an abnormal quantity of scrap and leaks from pierced tank linings as well as low-current efficiency the remedy lies in better furnace treatment.

A short circuit between two electrodes is not as serious as at first appears because there is a certain resistance due to conductors and contacts in series with each electrode and a number of parallel circuits. For example, if we have thirty pairs of electrodes and the series resistance amounts to one-quarter of the total across the tank, it is evident that a reduction of 75 per cent of the resistance in one of the thirty parallel circuits will but make it equal to four normal circuits out of the thirty and not draw any great share of the current. Then the increased current flow heats the conductors and contacts affected, and this increases their resistance. Finally, there is a certain rebate on the voltage side due to the lowered resistance of the tank when it comes to pounds of cathode per kilowatt-hour.

In general an economic balance is struck when about 5 per cent of the current is rendered non-effective by local short circuits.

B. Reaction

(a) *Deposition of Impurities*.—In the ordinary depositing tank the current consumed in the direct deposition of impurities is obviously negligible, as appears from the great purity of the cathode; in fact, it is an open question whether any of the traces of impurities

found in cathode copper are due to electrolytic action. Where insoluble or partly soluble anodes are used and higher voltages obtain, this item becomes measurable. An example of the first case is where arsenic is deposited in a "liberator" tank in copper refining, and of the second where iron is deposited in a copper-nickel refinery.

(b) *Gassing*.—A copper cathode rarely shows upon analysis above 99.95 per cent copper. The metallic impurities may total 0.02 per cent, still leaving some unaccounted for difference. Part of this is included electrolyte, but after all allowances are made it seems probable that hydrogen is present either as hydride or by occlusion. We know that some addition agents harden the cathode, and that this hardness may be removed by annealing. When all the copper in a liquor is plated out, as in the case of an electrolytic assay, the gassing does not begin and the voltage rise suddenly upon the exhaustion of the copper, but some gassing starts early and the voltage gradually rises. In the same way local conditions at the cathode due to the moderate circulation employed may cause the separation of a certain amount of hydrogen at the cathode in a normally operating cell. It seems probable, therefore, that a small proportion of the current may be diverted into depositing hydrogen instead of copper, and even a minute quantity of hydrogen will account for a measurable current on account of its very low electrochemical equivalent. For example, 0.03 per cent of hydrogen would take 0.9 per cent of the current. We do not know how much of a source of loss this condition is in straight copper work, but in nickel deposition it may be enormous, free hydrogen appearing in quantity at the cathode.

(c) *Valence*.—The efficiency is based upon the reaction

where copper acts as a divalent metal. It is evident that should the copper in the electrolyte be present in a cuprous salt, copper might be precipitated at an apparent efficiency of 200 per cent. Cuprous salts are undoubtedly formed to a certain extent at the anode, as shown by the cuprous chloride and metallic dust found in the slimes resulting from such a reaction as $\text{Cu}_2\text{SO}_4 = \text{CuSO}_4 + \text{Cu}$, although the latter is partly due to $\text{Cu}_2\text{O} + \text{H}_2\text{SO}_4 = \text{CuSO}_4 + \text{H}_2\text{O} + \text{Cu}$.

Cuprous sulphate is very unstable or we should gladly use it as the basis of an electrolyte, and it seems very unlikely that an appreciable amount exists at the cathode. The cuprous chloride found in the cathode when excess chlorides are allowed to accumulate in the electrolyte is doubtless due to direct reduction by the cathode as $\text{CuCl}_2 + \text{Cu} = 2\text{CuCl}$.

C. Cathode Shrinkage

(a) *Sulphatizing*.—A certain amount of the deposited copper is redissolved by the electrolyte. While copper is not normally soluble in dilute sulphuric acid, the oxygen dissolved in the electrolyte aids in a slow attack— $\text{Cu} + \text{H}_2\text{SO}_4 + \text{O} = \text{CuSO}_4 + \text{H}_2\text{O}$ probably expresses the complete reaction. As would be expected the action is particularly marked at the solution line and various expedients, such as painting or changing the solution level, have to be employed in order to prevent the cathode loops cutting through at the solution line.

The amount of this chemical action is indicated by the growth in the copper content of the electrolyte after correcting for anode impurities dissolving electrolytically and cuprous oxide in the anode dissolving chemically, and it is found to increase rapidly with increase of temperature of the electrolyte.

A fair figure is about 2 per cent of the deposited copper, and if we assume that half of this came from the anodes we have an apparent loss in current efficiency of 1 per cent.

(b) *Ferric Salts*.—If the anodes are not free from iron, converter anodes, for instance, and the resulting ferrous sulphate is allowed to accumulate in the electrolyte, there is a tendency, increasing with concentration, for this salt to be oxidized at the anode— $2\text{FeSO}_4 + \text{H}_2\text{SO}_4 + \text{O} = \text{Fe}_2(\text{SO}_4)_3 + \text{H}_2\text{O}$. This is particularly the case in insoluble anode tanks where the ferrous sulphate acts as a true depolarizer. This ferric salt is again reduced, either electrically at the cathode— $\text{Fe}_2(\text{SO}_4)_3 + 2\text{H} = 2\text{FeSO}_4 + \text{H}_2\text{SO}_4$ —or by the anodes and cathodes chemically— $\text{Fe}_2(\text{SO}_4)_3 + \text{Cu} = 2\text{FeSO}_4 + \text{CuSO}_4$. In either case there is a diversion of the current from its normal work and a corresponding loss in current efficiency. Under bad conditions, such as obtain in leaching copper ores, this loss may become very serious, but in straight refining work it should be entirely negligible.

(c) *Nodules, Etc.*—There is a certain apparent loss in efficiency due to mechanical shrinkage of the cathode from nodules falling into the slimes, chiefly due to inspection work on the tanks. This material is screened out of the slimes later, but is too contaminated to be considered legitimate production. Unless the deposit is rough the amount of this shrinkage will be but a small fraction of 1 per cent.

Summary

The nine sources of efficiency loss are always present, but any or all of them can be kept down to a very small quantity. On the other hand, most of them may become very serious under undesirable conditions. In general we can say that entire disregard of conditions may result in an efficiency as low as 60 per cent, poor work 85 per cent, good balanced operating 92 per cent, and efficiency regardless of expense 99 per cent.

Big Development Expected in Canadian Pulp and Paper Industry.—The large and increasing export of pulp to the American market is expected to cause great expansion of the Canadian pulp and paper industry. Several new plants are being erected and others are under consideration. Canada has the timber and waterpower and comparatively cheap labor to manufacture successfully. Canada will also have a large British market, including Australia and Africa.

Trade Agreements.—The Chamber of Commerce of the United States has received the report of the special committee, recommending that co-operative agreements be permitted under Federal supervision, where natural resources are involved. A condition is imposed, viz., that the agreements tend to conserve the resources and promote safety work. The report has been submitted to several commercial organizations for approval. The plan would empower the Federal Trade Commission to provide a method under which an industry may operate to the common benefit of producers, consumers and workmen. W. L. Saunders, chairman of the board of the Ingersoll-Rand Co., is chairman of the committee.

Manufacturers of Oxygen and Hydrogen in Germany Combine.—The leading oxygen and hydrogen producers in Germany, viz.: The Griesheim-Elektron Co., the Linde Refrigerating Machinery Co. and the German Oxyhydric Co., which between them control about 30 factories have formed a selling combine. Oxygen is said to be selling for 70 pfennig per cubic meter to private consumers and hydrogen for 40 pfennig.

The Nature and Origin of Petroleum and Asphalt

By Clifford Richardson

The writer has advanced the theory* that the origin of petroleum is to be attributed to relations of surfaces and films; that is to say, of films of certain types of natural gas, either as gas or, under pressure at the levels where it exists, in a liquid state, to surfaces of solids, the oil "sands" with which the former comes in contact at considerable depth below the earth's surface. The correctness of this theory seems to be emphasized by the fact that petroleum, wherever it occurs, is accompanied in the "sands" by gas in greater or less amounts, in many cases, in considerable excess. In regard to the origin of the gas no attempt will be made to draw a definite conclusion, as too little evidence is available to permit doing so.

While the writer's conception in regard to the origin of petroleum is purely theoretical, it is suggested and confirmed by studies of the nature and origin of one of the more solid forms of bitumen, that of the asphalt found in the well-known pitch lake in the Island of Trinidad, British West Indies. It appears that a petroleum, existing at considerable depth at that point, is converted to a more solid form of bitumen, asphalt, by coming in contact and being thoroughly emulsified with an aqueous paste consisting of clay, in a colloidal state as regards water, and very fine sand, which is in a colloidal state as regards the highly viscous bitumen. The clay and sand occur as a mud in a spring through which the oil breaks out before reaching the surface and with which it becomes intimately associated, owing to the strong evolution of gas which accompanies the oil as the pressure is released.

The deposit lies in a bowl-like depression, evidently the crater of an old mud spring or volcano, covering a superficial area of about 114 acres and having a depth of more than 135 ft., as shown by a boring made with a wash drill. The boring was necessarily discontinued at this depth, as, owing to the movement of the pitch, the pipe so far departed from the perpendicular as to prevent further work. This movement is due to the evolution of gas on the release of the pressure, to which it has been subjected, on reaching the surface, which is an original component of the petroleum as it is found in the oil "sand." The entire surface of the deposit is in constant motion. It is sufficiently solid to permit of driving a horse and cart over it, and to support, with constant attention, a railroad track for gathering and shipping the asphalt. From its form and environment it is known as a lake. It lies about half a mile from the sea at an elevation of 138 ft. above it.

The material of the deposit is a most unique geophysical phenomenon. At whatever point on the surface or whatever depth it is collected it is found to be of extremely uniform character, as appears from the following data:

AVERAGE COMPOSITION OF TRINIDAD LAKE PITCH IN CIRCLES

	Bitumen by CNS, per Cent	Mineral Matter, per Cent	Undetermined, per Cent
Circle 2, 200 ft. from center.	55.02	35.41	9.57

At a depth of 135 feet	54.66	35.90	9.44

*Jour. Ind. & Eng. Chem., Vol. 8, No. 1, page 4, 1916.

In the preceding figures data are given in regard to material, one component of which, water, has been removed by pulverizing and exposure to the air. As a matter of fact, the water present is as constant in amount, 29 per cent, as that of the other components. It is evident that the conditions under which the asphalt is formed involve a state of equilibrium between the components.

Including the water, the composition of the asphalt is as follows:

	Crude Trinidad Asphalt, per Cent
Water and gas.....	29.0
Bitumen soluble in cold carbon disulphide.....	39.0
Bitumen adsorbed and retained by the disperse mineral matter.....	0.3
Mineral matter on ignition with tricalcium phosphate.....	27.2
Water of hydration of clay.....	4.2

There is a constant influx of new material into the deposit near its center. This is, however, of different character from the main mass. It is, evidently, a freshly formed emulsion of the petroleum and the mud of the spring through which the oil rises to the surface. As a result it is of a very soft character, and can be readily molded in the hands, containing an excess of water not a part of the emulsion. In the course of years this soft material hardens and becomes of the consistency of the main mass of the deposit. This is, no doubt, to be attributed to the surface action which goes on between the colloidal mineral matter and the oil with which it is associated, and it has been observed that where the asphalt has overflowed the rim of the deposit and been exposed, probably for centuries, the surface action has gone further and the bitumen has been converted to a harder form than that found in the main deposit; in fact, differences in this respect can be found between the material near the center of the main deposit and that near its edge.

The origin of this asphalt having been demonstrated to depend upon the relations between heavy petroleum and mineral matter in a colloidal state, the origin of the petroleum itself, it seems reasonable to infer, is to be attributed to a similar condition of affairs in which the natural gas, from its relation to the surfaces of the oil "sand," is converted into petroleum.

It must, of course, be recognized that the surface action going on between a dense petroleum and mineral matter, much of it in a colloidal state as regards water, must be a much more rapid one than between a natural gas and a coarser oil "sand" with which it is brought in contact. But within long periods of time the latter must be quite similar to the former and should account for the origin of petroleum, especially in view of the fact that natural gas consists principally of methane and ethane.

Some natural gases contain hydrogen-sulphide and carbon-dioxide. From the first the petroleum containing sulphur should be derived, although they can also originate in the contact of the oils with sulphur and its compounds existing in the oil "sands"; in fact, free sulphur has been isolated from a Texas petroleum. Carbon-dioxide is an unusual constituent of natural gas, although it occurs in California in a McKittrick well to the extent of 30 per cent. In some of the gases in Trinidad, however, it exists in considerable amount, reaching 33 per cent in a gas which occurs in wells near the asphalt deposit. It is worthy of note also, that in the limited area in which oil wells have been sunk the gas encountered is of very variable composition. Analyses of a number of them, furnished by the writer, have

been made by the U. S. Bureau of Mines, which afford the following data:

COMPOSITION OF GAS FROM TRINIDAD, B. W. I.						
Identification No.	CH ₄	C ₂ H ₆	CO ₂	O ₂	N ₂	H ₂ S
1	85.1	4.1	9.8	.0	1.0	.0

a—H₂S, 2.9 per cent. b—H₂S, 0.1 per cent.

The California gases which are associated with highly asphaltic oils are nearly as variable as those of Trinidad in the percentages of methane and ethane present. They are also characterized by the fact that they carry considerable percentage of carbon-dioxide, in one case as high as 30.4 per cent. One contains a considerable percentage of hydrogen sulphide and the other carries none. In the Oklahoma and Kentucky gases, from which originate petroleum of a semi-asphaltic nature, carbon-dioxide is present to a notable extent. In the gas associated with the purely paraffine oils of Pennsylvania this gas is not found. The question arises whether its presence bears any relation to the formation of asphaltic petroleum. That of hydrogen sulphide might be regarded as having something to do with such a form were it not for the fact that it is absent from the Cali-

formia gases. The main mass of the gases from the various fields consists of methane and ethane, notwithstanding which fact the petroleum derived from them are markedly different in their characteristics. In the writer's opinion, this leads to the conclusion that the character of the petroleum derived from natural gas is to an important degree dependent upon that of the surface of the oil "sands" with which the gas contacts.

This is the thesis upon which the writer's theory of the origin of petroleum is founded; that is to say, while the gas from which petroleum originates is largely a mixture of methane and ethane, the petroleum originating from these gases varies in character, depending upon the state of subdivision and character of the surface presented to the gases by the "sands" and with which they come in contact. The result is, of course, influenced to a certain degree if the natural gas contains hydrogen sulphide, and apparently, also, to a considerable extent if there is a larger percentage of carbon-dioxide present, in this case asphaltic oils being formed.

In certain fields natural gas occurs which is not associated with petroleum. In this case it must be assumed that the gas does not remain in contact with the "sands" for a sufficient length of time to accomplish this, or the surfaces are not such in area or in character as will bring about its condensation to petroleum, the time factor being an important one.

New York City

New Developments in Nickel Industry.—The new refinery of the International Nickel Company in Wexford, Ontario, will be completed in about twelve months. Actual operations on the building of another refinery for the British-American Company will soon be commenced. These developments will make greater demands on Ontario for nickel ore. The value of the nickel output of Canada for 1916 is estimated to be \$23,000,000. The first and largest producer is the International Nickel Co. (Ambrose Monell, President), which does its refining in New Jersey, but smelts the matte in Sudbury, through the Canadian Copper Co., which it controls. The other corporation is the Mond Nickel Co. of Great Britain, whose head is Sir Alfred Mond, the prominent Liberal member of the British House of Commons. The Mond Nickel Co. also smelts its ore into matte at Coniston, Ont., and the matte is refined at Clydach, Wales, those works being greatly enlarged in 1914. The International Nickel Co. takes practically all of the 59,000,000 pounds which is shipped to the United States, and the Mond Co. all of the 12,000,000 pounds, which goes to Great Britain.

A third corporation was organized in July, 1913, under the name of the Canadian Nickel Corporation, but in the following month the name was changed to the British-American Nickel Corporation, and its plans are now taking more definite shape. The company bought up the nickel interests of the late John R. Booth and others, and now controls 17,000 acres of Sudbury lands, and has obtained the Canadian rights to a Norwegian process known as the Hybinette (after the name of one of the members of Hybinette, Borthen & Henriksen, who operate the only large successful mine of Norway at Evje, refining at Christiansand). It is claimed that with this process nickel can be produced 99 per cent pure. The nominal capital of all the Canadian nickel companies is about \$100,000,000. The capital of the International Nickel Co. is \$62,000,000, but of this only \$2,500,000 is in the Canadian Copper Co. The capital of the British-American Nickel Corporation is \$30,000,000. Mr. E. P. Mathewson, the well known Anaconda metallurgist and manager of the Washoe Reduction Works, has gone to Canada to assume the management of the British-American Company.

The Utilization of Waste Heat for Steam-Generating Purposes*

(Concluded from Vol. XV, page 708)

Beehive Coke Ovens

While it is true that beehive coke ovens are gradually being replaced with by-product ovens, there are still a very large number of the former in operation. Since there are few, if any, coals from which good coke can be made in beehive ovens that cannot be satisfactorily coked in by-product ovens if properly handled, it is questionable whether more beehive ovens will ever be built. On the other hand, it will be a number of years before all of the existing beehive ovens can be replaced by the more modern type.

The total coke production of the country in 1913 was 46,300,000 net tons, and of this quantity the production of by-product ovens was 12,715,000 tons, or 27.5 per cent of the total. The total estimated production in 1916 is 55,000,000 net tons, of which approximately 19,000,000 tons, or 34.4 per cent, will be produced in by-product ovens. By 1918 it is estimated that the production from by-product ovens will be somewhat over 50 per cent of the total production of the country.

It is not in the province of the present paper to discuss the merits of the two systems. This class of waste heat is dealt with here because of the very remarkable results that are being secured from modern waste-heat boilers utilizing gases from beehive ovens, and because of the possibilities of saving, due to this utilization, until such time as beehive ovens are replaced. Furthermore, there are available figures from boiler installations made a number of years ago for this class of work, and from a comparison with the results secured to-day the great advance in the design of waste-heat boilers may be readily seen.

From the nature of the beehive oven coking process, the quantity of gas available from each oven is large. These weights will vary with the analysis of the coal coked and the class of coke being made. The analysis of the gases escaping from the individual ovens will vary widely during different periods of the coking operation. Where a large number of ovens, however, are connected by a single flue to a boiler, or boilers, the average analysis at the boiler entrance will not show a particularly wide variation due to the fact that different ovens in the range or block are at different stages of coke making. At certain periods during operation large quantities of carbon monoxide pass off from the ovens and burn in the flues; in no plant investigated has there been noticed any secondary combustion within the boiler. For estimating purposes, the gas weight available may be taken as from 6 to 7 lb. per pound of coal coked per hour.

The temperature of the gases leaving the individual ovens is high, probably averaging between 2000 and 2200 deg. The temperature of these gases as they enter any boiler that is installed will depend upon the length, design and location of the connecting flues. Some typical entering temperatures are given in Table 5.

As far as is known, the first water-tube boilers installed in this country for this class of waste-heat work were placed in operation in 1900 at Greensburg, Pa. Due to improper design of connecting flues, these boilers were not successful in the utilization of the waste gases, and shortly after their installation were changed to coal-fired boilers.

*A paper read before the American Society of Mechanical Engineers on Dec. 16, 1916, in New York. All temperatures in this paper are given in degrees Fahrenheit.

Rather complete figures are available from three different plants in which boilers are installed for this class of work, the first two representing early waste-heat practice and the third representing the modern waste-heat boiler.

TABLE V—RESULTS OF TESTS OF WASTE-HEAT BOILERS FOR BEEHIVE COKE OVENS

Approximate transfer rate (R)	4.7	3.2	5.6	6.8

¹Three boilers, each of 3600 sq. ft. heating surface.

²Temperature leaving ovens 1970 deg. Fahr.

The first plant is that of the Priestman Collieries, Ltd., near Newcastle-on-Tyne, England. Here a Stirling boiler, rated at 161 hp., was connected to 22 beehive ovens producing coke from an average of 3800 lb. of coal per hour for the 22 ovens, or 173 lb. per hour per oven.

The second is at the York Run, Pa., plant of the H. C. Frick Coke Company. In this installation there are three Stirling boilers having approximately 3600 sq. ft. of heating surface each, though the boilers were rated at the time of purchase as 300 hp. each. These three boilers were connected to a range of 50 ovens, and during the week devoted to boiler testing, there were on an average 44 ovens in service which were coking coal at the rate of 13800 lb. per hour, or 314 lb. per oven per hour.

It has not been possible to secure permission to name the owners of the third and distinctly modern installation, although they have kindly consented to the publishing of some of the results secured from the first unit put into service. This installation consisted of a Bab-

cock and Wilcox boiler 18 sections wide, each section being made up of twenty-six 20-ft. tubes and containing 10,200 sq. ft. of heating surface. The boiler is equipped with a superheater and furnished with a turbine-driven induced-draft fan.

During the time the tests were run on the Babcock and Wilcox boiler the ovens were being operated to meet plant demands for coke, some ovens making 24-hour, some 36-hour and others 48-hour coke. The speed of the fan connected to the Babcock and Wilcox boiler was regulated to handle an approximately constant weight of gas, and as ovens were cut in or cut out, other boilers would be put into service and taken off again when the gas weights were reduced. Because of this fact it was practically impossible to determine the actual amount of coal coked corresponding to the capacity developed by the Babcock and Wilcox boiler. It is possible, however, to check pretty definitely the gas weight passing through the boiler, and from this weight approximate the coking rate corresponding to the horsepower developed.

The performance of the first boiler unit has been so satisfactory that the owners have purchased, since its installation, six additional units for use with their ovens. These are similar to the one described, except that they are 27 sections wide instead of 18, each unit containing 15,300 sq. ft. of heating surface, or a total of 9180 hp. for the six units.

The results of two of a series of tests on this Babcock and Wilcox boiler, together with the results secured at the other two plants described, are given in Table 5. In this table the gas weights, while approximate, are certainly within 10 per cent of the actual weights.

The baffle arrangement in the boiler at the Priestman Collieries is not known. It is probable, however, that the gas-passage areas were somewhat larger than standard, as the draft loss through the boiler is considerably less than would be expected for an equal weight of gas in coal-fired practice. The exit temperature is high but, considering the design of boiler and the weight of gas, cannot be considered excessive. In the report covering the series of tests from which this was taken, a statement is made to the effect that the capacity obtained did not represent the maximum, as, due to a

FIG. 7—REHEATING FURNACE AND WASTE-HEAT BOILER ARRANGEMENT

leaky damper, all of the gases from the ovens were not passed through the boiler.

In this plant the boiler was at the end of a range of 22 ovens. The flue was thus rather short, and because of the very low draft requirements of the ovens and natural-draft stack, provided sufficient draft for proper oven operation.

The test at the Frick plant extended over a full week's run of 168 hours. As stated, 44 of the ovens were in operation during the test, the ovens making 48-hour coke and half the number being charged each day with the object of maintaining even gas conditions. Gas weights and temperatures did vary considerably throughout the week. The lowest temperature noted was approximately 1500 deg., while the highest was 2075. The gas weight here corresponds to about the weight that would be passed through the boilers if they were being operated at about rating, coal-fired. The baffles in these boilers were standard, and the draft loss checks the statement made as to rating.

Under such conditions the exit temperatures, which varied during the test from approximately 475 to 550 deg., and averaged, as given, 490 deg., are no lower than might be expected.

The boilers at the Frick plant were located at the middle of a range of 50 ovens, so that the length of flue on either side was not excessive, and the draft requirements could be readily met by a stack 150 ft. high.

In Tests 3 and 4 the interesting features are the low exit-gas temperatures and the high capacities. The exit temperatures of 463 and 477 deg., for ratings of 172 and 192 per cent respectively, are lower by a considerable amount than would be obtained with coal-fired boilers at equal ratings. The design of the boiler to give the high heat-transfer rates noted offers sufficient explanation for these temperatures. In other tests of the Babcock and Wilcox boiler in this series, where the gas weights were such as to give approximately 96 and 128 per cent of rating with entering-gas temperatures of 2013 and 1811 deg., the exit temperatures were 437 and 428 deg., respectively.

At this plant the boilers were at the end of the blocks of 100 ovens and the connecting flues were of considerable length. This explains the necessity for the greater draft suction found at the boiler inlet in this boiler as compared with that in the plants previously described. The draft loss through the boilers is high, but is no more than would be expected when the weight of gas and the area of gas passage are considered. The fan, as stated, was turbine-driven, and a large proportion of the power required for this drive was returned through the exhaust to the feed water.

In this class of work the saving due to the utilization of waste heat is solely in the value of the steam generated. The amount of such saving may be approximated from the boiler capacities given in Table 5. As stated, the gas weight available will be approximately 6.5 lb. per pound of coal coked per hour. On this basis it will be noted from Tests 3 and 4 that 1 hp. was developed for 11.0 and 12.2 lb. of coal coked per hour, respectively, and it would seem conservative to state that with the modern design of waste-heat boiler a horsepower may be developed on the waste gases from 15 lb. of coal coked per hour. At such a return, even granting that beehive ovens will ultimately be replaced with by-product ovens, it would seem that, in numerous plants, an installation of waste-heat boilers would pay for itself many times before such a change could be made. It would be entirely possible, too, in these installations, to design the boilers in such a manner that at the time of replacing the beehive ovens the boilers could be dismantled and reset either for burning coal

or coke breeze, or to be fired with by-product coke-oven gas.

Heating Furnaces

The first boilers for any class of waste-heat work were unquestionably installed with heating furnaces of different descriptions, and the early history of boilers with heating furnaces is in reality the early history of the utilization of waste heat in general. While the writer does not know the actual date of the first installation, it is certain that it was previous to 1872. Before that date such boilers as were used in connection with heating or puddling furnaces were of the cylinder or two-flue design.

An article in the *Iron Age* of April 6, 1893, describes the early installations of water-tube boilers for this class of work and gives some more or less complete results of the performance of a number of these boilers. The first of these installations was made at the plant of the McCullough Iron Works, Wilmington, Del., in 1874, and consisted of two boilers of the Babcock and Wilcox design made up of seven sections of six 16-ft. tubes. Each boiler contained 860 sq. ft. of heating surface and in accordance with the practice of the day were rated on the basis of 11½ sq. ft. per horsepower, or 75 horsepower. To quote the journal mentioned: "These boilers, erected seventeen years ago, have been in constant use ever since and have given entire satisfaction."

¹Optical pyrometer.

²Varied at different periods of furnace operation from 604 deg. to 920 deg.

³Tests 3, 4 and 5 on same boiler. No. 3 represents 12-hr. period during which the structural mill was in operation, No. 4 a 12-hr. period with the mill not operating, and No. 5 a continuous run of 104 hr. during which the mill operated 56 hr. and was not in service 48 hr.

A number of boilers similar to these were installed after 1874 in the different iron and steel plants throughout the country. Test 1, Table 6, is representative of the performance of this design of boiler. This test was conducted by J. de Kinder at the plant of the Pennsylvania Bolt and Nut Company, Lebanon, Pa. At this same plant a test on a cylinder boiler in the same service showed exit temperatures considerably in excess of 1000 deg. as compared with 542 deg. for the water-tube boiler, and this temperature difference probably represents the difference in efficiency of the two types of boiler in this class of work.

It is of interest to note that the early waste-heat water-tube boilers with heating furnaces were of the three-pass design. There were, however, a number of factors in heating-furnace work which enabled satisfactory results to be obtained from a design that later was considered more or less impracticable for other classes of waste-heat work. The chief of these was the fact that the draft required at the outlet of the ordinary heating furnace was very low. The boilers were ordinarily set directly over the furnace, and the draft loss between the furnace and boiler was negligible. Furnaces were not driven at the time of the early in-

stallations at a rate that is at all comparable with present-day capacity, and the gas weights to be handled were very low. Further, the boilers were wide and long compared to the height, so that the gas-passage areas were large in comparison to the heating surface. The high exit temperatures ordinarily found enabled a given height of stack to give a greater draft than would the same height under coal-fired conditions.

In 1892 a type of single-pass waste-heat boiler was introduced by The Babcock and Wilcox Company. It is not quite clear why such a design was developed, but the presumption is that with increased furnace capacities the draft loss through a sufficient amount of heating surface in a three-pass design was great enough to interfere with the operation of the furnace. These boilers were of standard sectional Babcock and Wilcox design, but with tubes of 8, 9 and 10 ft. in length. The heating surface required to cool the gases sufficiently was obtained in the height of the boilers, and these were made from 18 to 27 tubes high.

The first boilers of this description were installed in the rolling mill of N. E. Ayre and Company, Portland, Ore., in 1892; one boiler being set over a box-scrap-heating furnace and the second in connection with a small billet-heating furnace. The *Iron Age* article, to which reference has been made, gives some figures on the performance of these boilers, but inasmuch as no temperature or draft measurements are reported, the figures are not included in Table 6. There are included in this table, however, results secured from a boiler of similar design installed in 1901 at the plant of the Cambria Steel Company, Johnstown, Pa. This boiler was of the single-pass type, made up of 10 sections of 27 tubes 10 ft. long and rated at 300 hp.

The results as compared with the earlier three-pass boilers are considerably in favor of that type. Some 7500 hp. of the single-pass design were installed, and in general the results secured were considered commercially satisfactory. Occasional installations of this design of boiler are still made. Because of the construction the boiler was expensive, and probably for this reason was never as popular as the next design of single-pass waste-heat boiler.

This was the Cahall waste-heat boiler, introduced in 1894 by the Aultman and Taylor Machinery Company. This was a single-pass vertical boiler in which the gases were introduced through an annular ring in the mud drum. Baffles were placed in the cone between the tubes with the object of throwing the gases into the tubes, but in view of the temperatures frequently encountered, it is questionable how long such baffles remained in place.

The results secured with this type of boiler were about in line with those of the previous single-pass type, though for a given set of conditions the exit temperatures were probably slightly higher. The Cahall boilers were popular, however, in the iron and steel industry, and over 20,000 hp. were installed. A number of these boilers were fired with blast-furnace gas and were not, therefore, waste-heat boilers.

Other types of boilers were used in this waste-heat work, but the three designs described were by far in the most general use. All of the boilers used were such as to give a minimum draft loss for the amount of gas to be handled, and in this way interfered in no manner with the operation of the primary furnaces.

In 1914 the first waste-heat boilers of strictly modern design and utilizing the theory of high gas velocity were installed for this class of work by the Bethlehem Steel Company. These boilers were of the general design described in connection with open-hearth steel practice, and were made up of 19 sections

of 17 tubes 16 ft. long. They were rated at 584 hp. each, were equipped with superheaters designed to give approximately 75 deg. of superheat, and furnished with motor-driven induced-draft fans. They were set in connection with two 28-in. structural-mill reheating furnaces, the approximate arrangement of furnace, boiler and fan being shown in Fig. 7. An extensive series of tests was run on one of these boilers in the early part of 1915. During these tests the structural mill was operated during certain shifts of 12 hr., while during other shifts the mill was not in service, though the furnace was kept hot. Under these conditions, since the temperatures were considerably lower while the mill was in operation, tests covering a wide range of gas temperatures are available, and the boiler performance under such conditions may be noted. Table 6 gives three of the tests on this boiler. Test 3 of this table represents a 12-hr. period during which the mill was in operation, Test 4 a 12-hr. period during which the mill was out of service, and Test 5 a continuous run of 104 hr., during which the mill was being operated for 56 hr. and was out of service 48 hr.

As in all previous tests, the interesting feature brought out by a comparison of early and modern results is the increase in capacity and decrease in exit temperatures in favor of the modern design. These lower exit temperatures further are secured with gas weights per square foot of heating surface greatly in excess of early practice.

The draft loss through the modern boiler, as indicated in the last three tests of Table 6, is reasonably high, though not nearly as great as found in open-hearth and cement plant waste-heat practice. Since the fan on this boiler was motor-driven, none of the power required for such drive could be reclaimed in the boiler feed. The amount of power required however was small, the maximum for the whole series of tests being about 2 per cent, while the average was 1.55 per cent of the total power generated by the boiler.

In this class of work the only saving through the use of waste-heat boilers is the value of the steam generated. This, however, is certainly a considerable item, and it would appear that there are numerous industrial furnaces that are similar to heating and puddling furnaces and where the temperatures are comparable, with which the installation of waste-heat boilers can show a handsome profit on any investment made.

Miscellaneous

While by far the greater number of waste-heat boilers in service are in the industries outlined above, there are numerous installations in plants of different character. In this miscellaneous class the number of installations in any single industry is small, but it appears advisable to make reference to certain of these, if only to give an idea of the wide and varied field for development in the use of waste heat.

Zinc Furnaces.—The writer has knowledge of over 11,000 hp. of waste-heat boilers set in connection with and utilizing waste gases from zinc furnaces. The temperatures in this class of work are high, being ordinarily in excess of 2000 deg. with certain designs of furnaces and probably averaging well over 1700 deg. with all classes. The draft requirements for the zinc furnace itself are low and, in fact, a number of furnaces are operated with a slight pressure at the exit. Because of these facts, the larger part of the installations with such furnaces has consisted of boilers that are practically standard in design. With

furnaces in which the ore treated is in contact with the gases, fears of the building-up on the tubes of an objectionable deposit led to a modification of boiler design to give more than the customary access to the heating surfaces, in order that all possible might be reached and brushed down should occasion demand. In refining furnaces, where the gases do not come in contact with the metal treated, there is, of course, no danger of such deposit, and standard boiler designs work out satisfactorily.

The results secured from these standard boilers have been entirely satisfactory, and from a commercial standpoint the return in all cases has shown that the expense of the installation has been more than warranted.

One of the first concerns using waste-heat boilers in this class of work for years installed units that essentially were of standard design. As the modern waste-heat boiler was developed, however, this company was persuaded to install such a unit, though the gas velocities were not quite as high as could be desired for the best results. No complete figures of the performance of the modern design as compared to the standard design are available, but the exit gas temperatures from the two designs are indicative of the higher efficiency of the former. One large installation of the modern type of waste-heat boiler has been purchased. These units are not as yet in service, however, and no results are available, but from our knowledge of waste-heat boilers in general there appears to be no reason why the performance should not be in line with known performances in other branches of the work.

Nickel-refining Furnaces.—The International Nickel Company (Orford Copper Works) has in service over 3000 hp. of waste-heat boilers set in connection with nickel-refining furnaces. As in the case of zinc furnaces the temperature of the waste gases is high. While it varies during different portions of the operation, the average is probably in the neighborhood of 1700 deg. when leaving the furnace. The boilers at this plant are of practically standard design, such as used for coal fuel, insofar as baffle arrangement is concerned. No complete test figures are available, but from data at hand the boilers are developing over 90 per cent of their rated capacity with exit gas temperatures of approximately 600 deg. With such a temperature leaving the boiler and a draft resistance through the boiler corresponding to about rating in coal-fired practice, the low draft requirement at the furnace exit is readily met by a 100-ft. stack.

These boilers, as stated, are of practically standard design. As compared with the exit temperature of 600 deg. actually being obtained it would be entirely possible, with the modern type of waste-heat boiler, to reduce this to 450 deg., corresponding to an increase of over 13 per cent in capacity. On the other hand, the design of boiler in use is developing approximately its rated capacity with gases that previous to 1911, the date of the first installation, were wasted. The success of the first units installed was such as to cause this company to duplicate them in later installations, and since these waste-heat boilers have made it possible to shut down a large portion of the coal-fired boiler plant, there was no apparent reason for changing the first design.

In this class of work, as with copper-refining furnaces, the saving due to the reclamation of dust within the setting is an item that compares favorably with the saving, due to the steam generated from the waste gases.

Gas Benches. Several installations of the modern

type of waste-heat boiler in small units have been made in connection with the illuminating-gas benches. The gas temperatures leaving the benches vary somewhat at different periods of the cycle, but where a number of benches are connected to a single boiler—and this is necessary to get a practicable weight of gas—the temperatures entering the boiler are reasonably constant. Complete figures are available of a test run on a modern design of waste-heat boiler in this class of work. The boiler in question has 1330 sq. ft. of heating surface, is equipped with a superheater, and furnished with an induced-draft fan. The boiler is connected to five gas benches, using an average of 211 lb. of coke per hr. per bench. The average temperature of the gases leaving the benches in the test was 1484 deg., while the average temperature entering the boiler was 1225 deg. The boiler test was run at the time the gas benches were first put in operation, and the temperatures, both leaving the benches and entering the boiler, are in all probability somewhat higher than would be the case after normal operating conditions were established.

Under the above conditions, the boiler cooled the gases to approximately 450 deg. (though this figure was undoubtedly affected somewhat by leakage at the damper) and developed 106 h. p., or 79.3 per cent of its rated capacity. The draft loss through the boiler was slightly less than 1 in. While this is not high as compared with other waste-heat work, when it is remembered that the boiler must be at some distance from the furthest bench and hence the connecting flue be of considerable length, and also that approximately 0.75 in. or 1 in. of draft is necessary at the bench outlets, the impracticability of a natural-draft stack, where a boiler is installed in this class of work, is obvious.

In the plant in question the waste-heat boiler generated not only sufficient steam for the requirements of the coal-gas section of the plant, which are low, but a surplus that was almost sufficient for the operation of the water-gas department of the plant.

Oil Stills. At least two installations of the modern type of waste-heat boilers have been made in connection with oil stills, though, aside from the statement to the effect that these boilers are giving satisfactory service, nothing definite on their performance is available.

In this class of work it would appear that the amount of gas available is dependent, to a certain extent, upon the operation of the still, though from reports at hand it would seem safe to figure on approximately 22 to 24 lb. of gas per lb. of oil burned under the stills. The temperature of such gas at a point corresponding to the boiler inlet is approximately 1000 deg., and because a number of stills are connected to a single boiler, this temperature is practically constant.

With the modern design of boiler, as in other waste-heat work, the draft loss is high, and as a draft of approximately 1 in. is required at the stills for proper operation, induced-draft fans are necessary in this class of work.

Embargoes.—From France the exportation of the following articles is no longer permitted: Oxalic acid, albumen, chlorine compounds, carbon chloride, iron or ordinary steel cutting tools, tools and detached parts, machine parts and all other articles in special steel except clock-makers' tools. From Norway copper substitutes and all kinds of rolled and drawn iron wire, condensed milk, cement and bamboo cases may no longer be exported.

FIG. 1—A VIEW OF THE SALT DISTRICT—LUMBER RAFTS ON THE RIVER

FIG. 2—TZULIUTSING—A VIEW FROM THE RIVER

The Production of Salt in Szechuen Province, Western China

By H. K. Richardson

Situated at the extreme western border of China is the isolated mountain province of Szechuen, the largest in area, the most populous and wealthiest province of China. Much has been written of the coal, copper, zinc, antimony and other mineral resources of this wonderful land of nature, but little has been published regarding

the work of the people. The activities of the Szechuenese that have made them famous all over China are: (1) The highly productive salt districts of the province; (2) the production of sugar and sugared fruits; (3) the fine silk, mostly crêpe, sent to all parts of China; (4) the great variety of skins or furs exported, 1,500,000 pieces passing the Chungking custom house per year, and (5) the vast quantity of herbs gathered for medicine, \$1,000,000 worth passing the Chungking custom house for export per year.

The most interesting of all these industries to the chemical engineer is the production of salt. The rela-

FIG. 4—DIAGRAM SHOWING THE SUCCESSIVE STEPS OF THE CHINESE SALT

tive importance of the salt production of this province to the total production in China is readily seen from the following figures:

1915, total consumption of salt in

China 3,366,000,000 lb.
1915, total salt produced in Szechuen.. 735,000,000 lb.

The Szechuen product is consumed locally and in the provinces of Hupeh, Kueichow, Yunnan, and Kansu, supplying probably 100,000,000, or one-quarter of the population of the republic with this necessity of life.

The salt-producing territory of the province is situated along the river bottoms and hillsides bordering the many streams between longitude 104 deg. and 110 deg. east and latitude 29 deg. and 31.5 deg. north. The whole area covered is about 32,000 square miles.

All of the salt produced is obtained by the evaporation of brine. The brine is obtained from three general types of wells:

1. Salt springs either on the surface or at the bottom of shallow pits. This type is found mostly in the eastern end of the district. The best illustration of this type is the well at Kwei Chow Fu.

2. Wells drilled through clay and soft rock to 1000 ft. This type of well is the most prevalent in the province, and is illustrated by the wells at Tai Ho Chen on the Chengstu-Wanhhsien postroad and Chien Wei Hsien on the Min River near Kiating.

3. Deep wells drilled through hard limestone to 3000 to 4000 ft. All wells of this type are found at Tzuliutsing, in the southwestern corner of the salt well district.

In this article the wells at Tzuliutsing, which are the

FIG. 3—MAP OF SALT DISTRICT (DOTTED LINES REPRESENT POST ROADS)

largest and most famous wells for salt production in China, will be described, while a future article will deal with the more numerous, smaller, but none the less interesting wells.

Tzuliutsing is a subdistrict made up of a combination of three market towns of the Fu Shun and Yung

FIG. 5—EMPTYING THE BAMBOO BAILER

Hsien districts of the province of Szechuen. It is 110 miles west of the treaty port of Chungking and 100 miles southeast of Chengtu, the capital of the province (see map, Fig. 3).

The history of these wells is obscure, but they are mentioned in the provincial histories of a thousand years ago. Inquiry as to how the wells were discovered reveals the fact that at the high stage of the river there is a spring on the hillside that bubbles out brine. The district takes its name from this spring, for Tzu Liu Tsing means "Self-Flowing Well."

There are three distinct sections to the district:

In the Deep Well Section the wells are driven through sandstone and are from 2500 to 4000 ft. deep. Natural gas is obtained from some of the wells in this section and used for evaporating purposes. This is the most important section and produces three-quarters of the salt of the district.

In the Medium Well Section the wells are from 1000 to 2000 ft. deep.

In the Shallow Well Section the wells are from 200 to 1000 ft. deep and coal is used to evaporate the brine.

The technique of the process in the three districts is the same except for the evaporating, since practice during more than a thousand years has made the process uniform at the various wells. There are no secret processes, and anyone is free to look around as he pleases.

The operations used to obtain the salt will be consid-

ered under the following heads: Well drilling, process and costs; pumping or drawing the brine, process and costs; transportation of the brine; evaporation of the brine, process and costs; transportation and cost of salt.

Well Drilling

After the location of a new well is decided upon, the first thing is to build a house, derrick and winding drum at that place. The derrick (Fig. 4, B) is made of pine trees. To get the necessary length several trees are spliced together; to get the needed cross-section three trees are bound together with a 1-in. bamboo rope, making a triangular log 20 in. on a side (see Fig.

5). To keep the binding bands tight wooden wedges are driven under the rope.

A pulley 2½ ft. in diameter, made of oak with sides extended to form a groove, is placed on the top cross bar of the derrick; the lifting rope for drills or bailer runs over this pulley, under another larger pulley (5 ft. 6 in. in diameter) held firmly in position by a weighted framework (Fig. 2, R) to the winding drum (Fig. 2, A). The pulley and derrick can well be seen in Fig. 6.

The drum resembles a ferris wheel laid on its side, and is made of wood and bamboo. There are no nails in its construction, all joints are mortise and tenon or tied with bamboo rope. The drum usually has sixteen sides and will wind from 54 to 65 ft. of rope to a turn. It is 7 ft. high and is set 5 ft. up from the ground so as to allow the draught animals to pass under the rope, which winds onto the framework near the bottom.

At the top of the framework is the brake. This is a bamboo tube split on one side and opened out its full width, making a bamboo piece 12 in. wide and the thickness of a bamboo. One end of the brake is firmly secured to one of the shed posts, while the other is tied by a bamboo rope to an adjoining post. To use the brake the brakeman pulls down on the bamboo rope until his whole weight is acting to tighten the band and slow down the drum to the desired speed.

FIG. 7—SALT WELL DRILLER HAND FORGED FROM NATIVE WROUGHT IRON

When lowering the bailer the drum gets up quite a speed, for it makes fifty revolutions in eighty seconds, the time necessary for the bailer to reach the bottom of a 2500-ft. well. The brake must be manipulated carefully, for the bailer must not strike bottom with its force unabated. Fig. 2, A, R, B, and Fig. 6 illustrate the whole apparatus.

The first operation in sinking the well is to quarry out a hole several feet in diameter and 200 ft. Chinese deep. (One foot Chinese equals 1.11 ft. English.) Into the center of this excavation a wooden pipe is placed. This pipe is made from "Song Mu," a wood similar to Georgia pine. The tree is cut into 10-ft. lengths, sawed in halves lengthwise and the heart gouged out to make a 6-in. semicircular hole. The two halves are then bound together, making a wooden pipe 6 in. inside diam. with sides 4 in. thick. These pipes placed end to end in the excavation, are accurately centered and made vertical, then secured in place by stone cribbing.

FIG. 6—WINDING DRUM AND DERRICK

This tube is, in fact, the guide by which the drilling is started, and unless they are carefully placed there will be trouble a-plenty in the future drilling work. More than a thousand years of experience have taught the Chinese that this work must be accurately done to insure a right start, so more care is exercised in this work than is usual in things Chinese. The top of the well is capped with a heavy piece of limestone, cut about 30 in. square and 20 in. thick where the 6-in. hole pierces it. These caps prevent the top of the wooden pipe from being split or abraded by the descending tools.

The drilling is done with a iron spud drill. To make the drill heavier and work better an iron rod is put into the bamboo casing above the drill proper. This serves to give a second blow each time the drill is dropped. (See Fig. 7 for details.) To start drilling the tools are lowered down through the wooden tubes until stone is reached. The tools are suspended by a

FIG. 8—DRILLING A WELL. THE LEVER ARM AND TOP OF DRILLING SET

split bamboo rope from the short end of a lever arm, the rope is adjusted until the lever arm is horizontal with tools resting on bottom.

To drill, the long arm of the lever is depressed by coolies, until the drill is lifted about a foot, when the arm is released and the drills drop. In this work a group of five or six men work on a scaffolding around the long lever arm; to depress the lever they put their right foot on the lever, which is carried down till it reaches the stops, when they step across to the bench opposite, thereby releasing the lever, which flies up, allowing the drills to drop. The movement of the lever is restricted in both directions by guide stops. The men then turn about and return, depressing the lever again. The lever is depressed as high as thirty times a minute, but fifteen to twenty would be nearer the average. Each time the drill raises the man at the well gives the rope a turn. One-half of the men who do the depressing of the lever cross in one direction while the others step in the opposite direction.

FIG. 9—TOOLS TO RECOVER LOST DRILLS, ETC.

The men work ten minutes then rest while the drill rope is being lengthened. Fig. 8 gives a good illustration of the arrangement of the drilling apparatus. The average drilling is 3 ft. in twenty-four hours. To drill an average 2500-ft. well six to twenty years is taken; three to five years only would be needed if the drilling were not interrupted by litigation, lack of capital, loss of tools and various other troubles. The average well takes ten years to become a producer.

The sand and dirt produced by the drilling is removed by the sand pump, a common bamboo tube 20 ft. long. To meet the emergency caused by breakage of rope and loss of tools, the Chinese have invented a wide variety of tools (see Fig. 9). If none of these tools accomplish the work, as a last recourse a new drill is let down and the lost articles slowly churned up. A lost bailer is treated in the same way.

At a well we visited the brine had given out at the 2600 ft. level, so they were drilling further. Since this well is a good average of the district the following data will be of interest:

Depth of drilling	2,600 ft.
Drop of drill per lift	10 3/4 in.
Drill size, Length	12 ft. 10 in.
Diameter	2 1/4 in.
Width of face	4 1/2 in.
Weight	160 catties or 208 lb.
Size of rope	three pieces of split bamboo, each piece 1/4 x 1 in.
Rate of drilling—average	3.33 ft. per twenty-four hours
Number of men	working lever—5; at well—2
Lever arm, Short side	20 in.
Long side	15 ft., center of effort of men at 9 ft.

FIG. 10—TRANSPORTATION OF BRINE COOLIE CARRIAGE

FIG. 11—TRANSPORTATION OF BRINE. FLIGHT OF DRAGON BONE LIFTS

When drilling a well either gas or brine may be struck, but as both are valuable no one complains. A few of the wells yield a little petroleum, but no use is made of it, for it burns with too smokey a flame. No attempt is made to refine it. It is probable that deeper drilling would unlock untold wealth for the province.

A Chinese well operator estimated that the average cost of drilling a well is to

1,000 ft.	3,000 taels or \$2,100 U. S.
2,000 ft.	7,000 taels or 4,900 U. S.
3,000 ft.	25,000 taels or 17,500 U. S.

It is surprising how accurate a Chinese is at arriving at an average. We have found that we could trust figures given as an average, even when the details are wrongly given.

Pumping or Drawing Brine

The brine obtained in the drilling is raised to the surface in bailers. These are bamboo tubes 60 to 110 ft. long and about 4 in. outside diameter. Each tube is made up of several bamboo tubes joined together by tapering ends. To prevent cracking and withstand the pressure, each tube is wrapped, for $\frac{1}{2}$ in. in every 2 in., with hempen twine sunken below the surface. A tube holds about 650 lb. of brine. A bamboo rope made of three braided strands is used to pull the bailer up out of the well. See Fig. 5 for bailer.

The motive power for raising the bailer is of four kinds: (1) Human beings; (2) water buffalo; (3) donkeys; (4) steam engines.

1. Human Beings.—

At some of the smaller wells sixty men and boys will be found slowly toiling to pull the bailer up. This is an old method, and at present rather goes against the grain of the Chinese to use it. The present year is the first time for over six years that it has been in use. The reason is that a very serious epidemic among the water buffalo has made these so scarce that only the wealthy wells can get them. During the epidemic last year one

well lost seventy of its herd of 100 buffalo. Only beggars and orphans are used on this work; they get a place to sleep, one meal a day and 50 cash, or a cent and two-thirds for a day's work.

2. *Water Buffalo*.—The most common motive power is the water buffalo. From five to seven of these big lumbering beasts are hitched to the winding drum. As the bailer nears the top of the well, a rag on the rope is the indicator, and as the load lightens the drivers whip the beasts unmercifully to speed them up. This cruel treatment to a slow plodding animal causes short life. The animals last about four years on the average, when they are traded off for fresh animals. Some of the wells make eighty pulls a day; a pull requires the steady exertion of the buffalo for from ten to twenty minutes, according to the depth of the well. A set of buffalo make two turns of the wheel and then are given eight hours of rest and wallowing in the river. Thus the animal does about thirty minutes' work every eight or nine hours, night and day, as long as it lasts.

3. *Donkeys*.—A few wells use donkeys on the drum. Nine donkeys are used per shift. Ten shifts of animals are provided; each shift is used once and then rests until its next turn. They are a little quicker than the buffalo, but do not seem to be in much favor.

4. *Steam Engines*.—Some ten years ago an English salesman sold a well owner a steam engine to raise the brine. He reckoned five buffalo to be the same as 5 hp., so a 5-hp. engine was delivered. It lacked the needed power and was a flat failure. It has served as a terrible example at the hands of the old conservatives and the told-you-so's, and has discouraged the buying of more machines. About four years ago an engine of Chinese make was tried, and after lots of trouble it worked. Now there are several, mostly of Japanese make, in the territory.

The engines are used in two ways: first, a wire cable is wound around the old winding drum and carried over a pulley on the engine shaft, and the bailer is brought up by its bamboo rope in the old way; second, a half-inch steel cable is connected to the bailer and the cable wound up directly on the winding drum of the engine.

The best example of these engines now in use is a Japanese single-cylinder hoisting drum set with a separate boiler. The engine is a 12-in. stroke with a $7\frac{1}{2}$ -in. cylinder. It is rated at 25 hp., but was only developing

FIG. 12—TRANSPORTATION OF BRINE. BAMBOO PIPE LINES

13 when we saw it. The boiler was 4 by 10 ft., vertical fire tube, and could not supply enough steam for the work. The piping was too small, so there was a big loss in pressure from this source. This engine was making 150 pulls per day to eighty pulls when using buffalo. A pull took eight minutes as against twelve the old way; most of the lost time is due to waiting for the steam pressure to come up. There is a good field here for an enterprising company who will study the requirements of the work and aim to meet them with as cheap a set as possible.

A few years ago a gas engine was tried out, but an explosion in the gas bag due to back fire made it *persona non grata* with the Chinese. Although it did its work fairly well, we saw the dismantled engine being carried out of town last fall.

That we may gain some idea of the size of these wells, the following data, obtained at a well managed and representative well of the district, are given:

Name of well....."Hong Hai Gin"—Red Sea Well
Depth of well.....2,600 ft. Chinese or 2,888 ft. English
Bailer—Bamboo.....3¼ in. O.D. and 2¾ in. I.D.
Length.....105 ft. or 117 ft. English
Contents.....520 catties or 676 lb. of brine
Number of lifts per day.....30
Cost of bailer.....\$12.50 U. S.
Length of use.....one year, one spare on hand
Foot valves.....cost 3 cents, use 15 per month
Time taken per trip.....up, 10 to 12 min.; down, 1½ min.

Bailer rope—Bamboo—1 in. in diameter of 3 strands, each strand made of 30 strips of split bamboo, each strip is 3/16 in. wide by 1/64 in. thick, thus 90 strips per rope. Each length of rope from 24 to 28 ft. long and costs 10 cents. Whole rope costs \$12.00.
A rope lasts 20 days and is replaced 5 lengths per day.

Winding drum—60 ft. circumference, 18 ft. diameter, 6 ft. high.
Buffalos—On drum per trip.....5

Total herd.....80
Original cost each animal.....50 to 80 Taels or \$35 to \$56
Used two, three to ten years, average 4 years, then traded in at about \$15.00.
Feed cost per day.....14 cents each animal

Workers—2 shifts of 12 hours each.
2 men each to cook, repair rope and let out brine.... 6
9 men to feed and carry water for buffalo..... 9
24 men to drive buffalo.....24
3 foremen for men and 1 well boss.....4
7 office help at the well.....7

Help, total.....50

Wages—Ordinary men.....2 to 3,000 cash or \$2.30 a month
Tub men—let out brine.....3 to 4,000 cash or \$2.70 a month
Well boss.....5 to 6,000 cash or \$3.00 a month

Production—Brine strength,
24 oz. of salt per pound of brine or a 15% solution.
Brine lifted per day.....2½ tons, average
Salt in above per day.....4.05 tons, average

Equipment Costs—Derrick, Drum, House, etc.—Taels 4,000 or
\$2,800 U. S.

This well took over six years to drill and has been in active operation for over 100 years. It is the property of a wealthy clan.

From the above data we are enabled to work up a cost sheet of this well; the details follows:

FIG. 14—TRANSPORTATION OF BRINE. LOADING BRINE BOATS

COST OF RAISING BRINE AT THE RED SEA WELL

Production per day.....	\$,100 lb. of salt
Labor Charge.....	Per Day
Feed for buffalo, 80, at \$0.14 each.....	\$11.20
Coolies' wages:	
1 at \$3.00 per month.....	\$3.00
2 at \$2.70 per month.....	5.40
47 at \$2.30 per month.....	108.10

\$116.50/30 3.88

Animals Replacement Charge:

Average use of a buffalo, 4 years, thus, with 80 animals, 20 are replaced per year.

Purchase price.....\$45.00
Traded in price.....15.00 Loss is \$30.00

Thus 20 X \$30.00 is \$600.00/360..... 1.67

Materials:
Repairs to rope, valves, tools, etc..... 1.00

Interest on Investment.....\$17.75

Equipment.....\$2,800
Buffalo.....3,600
Well value estimate.....10,000

\$16,400 at 10% is \$1,640/360 4.56

Total manufacturing cost.....\$22.31
Office incidentals estimate..... 1.69

\$24.00

The manager of the well gave us these details, and also gave us Taels 50 or \$35 as his estimate of the total daily running expenses of this well, including the office upturn.

From these figures it is seen that the cost of raising enough brine to give a pound of salt is 2400 8100, or 0.296 cents per pound or 11.5 cash per catty.

Transportation of Brine

When the bailer reaches the surface of the well the tubeman pushes it aside over a tub, and with an iron hook holds the foot valve up, the brine rushes out into the tub and flows away to the evaporating pans. (See Fig. 5.)

To get the brine to the evaporating pans use is made of gravity wherever possible. To this end bamboo tubes are placed end to end to make a pipe line. These pipe lines can be seen going up hills, through houses and sometimes under the river. It is hard to dig a foundation without striking either an active or an abandoned pipe line. All pipe lines lead to natural gas wells. When it is necessary to raise the brine beyond the level of its source the Chinese made use of several ingenious schemes.

Coolie Carriage.—One of the simplest of these schemes is to elevate a tank upon a platform and have coolies carry the brine up to it in buckets and empty them into the tank. (See Fig. 2, D. E. and Fig. 9.)

Dragon Bone Lift.—A very common type of lift for use on the hillsides is the dragon bone lift. This lift is in use by the farmers for irrigating the fields and lifting water to moderate heights. This machine resembles a wooden chain pump laid on its side. It

FIG. 13—TRANSPORTATION OF BRINE. HORSE-DRIVEN WINDLASS AND BUCKET LIFTS

consists of a wooden jointed chain carrying thin oblong wooden vanes attached at right angles to the chain; the chain works in a long box open on the top and at both ends. The box is about 16 ft. long and has a cross-section of 6 in. deep by 10 in. wide. The chain with its vanes passes over a notched wheel at either end of the box. The upper wheel is turned either by a hand crank, by men working treadmill fashion, or by a gear and animals. The lower end of the box is placed in the brine and the traveling vanes entrap the liquid, which is carried up the box and discharged over the upper end. When the hill is high, cascades of five or more are needed. In this case each one is the feeder to the one which is above. (See Fig. 2, F. G. H. and Figs. 11 and 15.)

Windlass Lifts.—Sometimes an endless chain of buckets is arranged to lift from one level to another; sometimes it is one bucket only making an intermittent process. These are worked by hand crank, pulling or by horses through gears. (See Fig. 13.)

Compensated Bucket Lift.—From the long end of a lever a bucket is hung by a bamboo rope, while to the short end a stone that nearly compensates the weight of a full bucket of brine is tied. The fulcrum of the lever is on the top of a post and the rope passes down

the unloading. (See Figs. 14 and 15.) The longest pipe line is about 7 miles.

Evaporation of Brine

The brine from the various wells is conducted to the vicinity of the gas wells and there evaporated in open pans over gas flames. The burners are rented to the owners of the brine, who furnish the workers and all the apparatus needed in the evaporating work. Two kinds of salt are made, the cake or pan salt and the crystallized.

The outlines of the process for making pan salt is given in Flowsheet I. The process for the production of the salt crystals is a little different. In the first place the pans are more carefully prepared for they are more permanent, after which the scheme given in Flowsheet II is used.

The iron pans used for the evaporating are shallow segments of a sphere 62 in. in diameter and 4 in. deep. The iron is 3 in. thick at the center and $\frac{1}{2}$ in. thick at the edges. They are made of native cast iron and weigh from 1400 to 1600 lb. They cost 43 taels, or \$30.10. When used for making pan salt they will last thirty or forty heats before cracking, and when repaired are good for as many more. As the usual heat is four days, they last nine months. The discarded pans are traded in for part payment for new pans. The fifteen iron side plates are in fact a detachable side rim 6 in. wide, and are used so that the salt cake can be easily removed. These fifteen sides cost about \$9 a set and weigh 23 lb. each. In one evaporator house we visited there were 101 pans all making the salt cake. Fig. 16 shows a set of the pans and Fig. 2, N and O show

through the floor of the platform built over the tank. To lift the brine the bucket rope is pulled down until the bucket is filled in the lower tank, when the rope is pulled up and the bucket dumped at the higher level, 15 ft. above the tank. This scheme is also used to irrigate vegetable gardens from wells. (See Fig. 2, K, and in background of Fig. 10.)

Surge Tanks.—When the pipe lines are long and pass over wide valleys the pressure on the pipes is high, so a surge tank is placed at an elevation in the valley, slowing up the speed of the brine and easing up on the pressure. It is also found on the top of a hill where suction might cause the collapse of a tube. (See Fig. 2, J, and 12.)

All the pipes are bound with split bamboo, over a mixture of chalk and China wood oil, so that they are fairly satisfactory. They leak a little and it is no uncommon sight to see beggars digging up the salt-carrying earth under a pipe line and leaching it to get the salt. The pipe lines are rarely tampered with, for it is a criminal offense heavily punishable to disturb them.

In the part of the district where the brine has to be carried so far that the Chinese feel that a pipe line is too long, the brine is run into scows and poled up the river and unloaded. The dragon bone lift is used for

FIG. 15—TRANSPORTATION OF BRINE. UNLOADING BRINE BOATS

FIG. 16—EVAPORATION OF BRINE. SALT CAKE PANS

the construction for pan and crystal evaporation respectively.

When pan salt is made there is no attempt to get much draft under the pan—the leaks are plenty. The pan is set up on 2 x 2 x 10-in. stone legs and thin brick laid up around the edge to prevent the wind from blowing the gas flames. When making crystal salt the pan is set more permanently so a draft tube is provided at the back, while openings in the brick at the front provide for the needed regulation. (See Fig. 2, O.)

Gas Wells

The gas wells were originally driven for brine, but as they give off the gas, they are almost wholly used for the gas. To collect the gas a chamber of cement 7 ft. high and 10 ft. long is made around the well just below the ground and the wooden pipe cut out of this section. The gas arising collects in this chamber, the well is not capped as has been said, and no gas is smelled at the top, for the burners are situated 20 ft. higher than the level of the gas chamber and their burning sucks all the gas up the tubes. The gas pipes are 3-in. (inside diameter) bamboo tubes leading out of the top of the box. One well we were visiting served 200 burners, which were burning about 20,000 cu. ft. of gas per hour. When the brine rises and cuts off the gas supply a bailer is put down and the brine removed. This gives too much gas for a while and the pressure is relieved by lighting a big auxiliary torch, which serves as a safety valve. Fig. 16 shows such an auxiliary torch.

FIG. 17—NATURAL GAS WELLS—SURPLUS RELIEF BURNERS

The burners are made from bamboo tubes coated with a 2-in. layer of Chinese cement. Chinese cement is made from broken tile hammered fine, lime and sand or mud well mixed and hammered into place. Fig. 17 shows these burners, while Fig. 2, P and Q show the gas system.

The cost of evaporating is hard to calculate, but Sir A. Hosie estimates that it was 2 to 4 cash in 1884. (Report on province of Ssuch'uen, page 98.) The cost at the present time cannot be far from 4½ cash per gin or 0.15 cents per pound of salt.

If we add this value to the cost of raising the brine we have the following as the total cost of producing salt:

Raising brine.....	11.5 cash per gin or 0.236 cents per pound
Evaporation	4.5 cash per gin or 0.150 cents per pound
	16.0 cash per gin or 0.446 cents per pound

Under the present uniform tax administered by the Salt Gabelle a hundred gin or 133 1/3 lb. of salt pay a tax of \$2.50 silver. At an average of exchange of 1,500 cash per silver dollar this is 37.5 cash per gin or 0.967 cents per pound. Thus the salt at the place of pro-

FIG. 18—INSPECTING AND WEIGHING CAKES OF SALT CRYSTALS. NOTE GOVERNMENT STAMP ON THE CAKE IN THE SCALE. NOTE OVERLAND COOLIE CARRIAGE OF THE SALT TO EAST AND WEST

duction, duty paid, costs 53.5 cash per gin or 1.413 cents per pound. Fig. 18 shows the weighing of crystal salt at the tax office and its preparation for transport.

Road transport by coolies costs 12 cents per 120 lb. per day of 25 miles, or one-tenth of a cent per pound per 25 miles. Chengtu the capital is 150 miles from the salt wells, and salt retails there for 80 cash a gin or 2 2/3 cents a pound. As the salt well gin has 18 oz. and the retail gin 16 oz., there is some chance for profit. The retail price of salt is fixed by the government for each locality.

It is said by the Chinese that there are 10,000 wells in the district. Of these 5000 are active and 500 in process of drilling, while the rest are abandoned or in litigation. In 1904 Tzuliutsing produced 183,000 of the 279,433 tons of salt credited to Szechuen by the salt office. The 1913 production for Szechuen is given as 367,246 tons, and if Tzuliutsing produced the same proportion as in 1904, the 1913 production would have been 244,830 tons.

Most of the wells are not large producers, probably not over 10 per cent of the active wells will produce as much as the representative "Red Sea Well." If the remaining 90 per cent had only a production of half a

ton the average of the whole lot of wells would be only three-quarters of a ton per day, thus the daily production of the district, 677 tons, would come from 900 wells, and the remainder of the 5000 wells would be producing less than nothing. It is thus evident that either the number of the wells is wrongly estimated by the Chinese or that a fewer number are active.

Some one discovered that a few of the wells were pumping from the same pocket, so when the wells ran dry, water was run down into the deepest well, a 2500-foot well, and now twenty-three wells in an area of a square mile can be pumped. At present about 150 gal. of water a minute is run into this well for half a day at a time. Thirteen of the wells can pump continuously from the water thus supplied. In order that the owners of the pumping wells can be sure that they are getting what they pay for, rice hulls are fed in with the water into the big well.

The stopping of leaks in the well shows the ingenuity of the Chinese. When a fresh water leak threatens to impair the usefulness of the well, its location is ascertained, then a bunch of coarse grass is rammed down below the position of the leak. On to this grass a mixture of mud, lime and China wood oil is poured; this is allowed to harden to a cement. The drill is then put down and a hole drilled through the cement, the grass removed and the leak is effectually stopped. This is the same method which has been lately advised to be used in stopping the waste of natural gas from oil wells. One who thinks that all progress in technical matters is associated with the Anglo-Saxon race, will be very much surprised at the development reached in this district some thousand years ago. The trip is well worth its cost.

BIBLIOGRAPHY. There are three descriptions that have been given of this territory, 1904; Sir A. Hosie in "Report on the Province of Szechuen," British blue book, China 5 (1904), 1909; Mr. R. O. Jolliffe in "Our Share in China," page 113, etc., and Messrs. Head in "Mining and Scientific Press," Oct. 24, 1914, this is a translation of a French paper.

Electrolytic Behavior of Tungsten*

By Walter E. Koerner

The electrolytic behavior of tungsten has not been extensively investigated. Almost all of the earlier investigators have worked on the electrolytic deposition of metallic tungsten, their object being probably to produce tungsten in a tangible form by a relatively simple method.

The first researches upon the electrolytic reduction of tungsten were made from solutions of fused baths of tungstates. Zettnow¹, in an article published in 1867, describes a black amorphous powder of metallic tungsten which he obtained, along with sodium bronze, by the electrolysis of molten sodium tungstate. Hallopeau², obtained by the electrolysis of molten lithium paratungstate, with platinum electrodes, crystals of metallic tungsten. Stavenhagen³, however, under the same conditions, obtained no metallic tungsten, but only lithium tungsten bronze. Scheibler⁴ and Knorre⁵ describe in their papers a large number of tungsten bronzes which they obtained by the electrolysis of molten tungstates.

Martin⁶ obtained impure metallic tungsten by the electrolysis of tungstic acid dissolved in molten cryolite, analogous to the method of preparing metallic aluminium. The electrolysis of molten baths of halogen or oxyhalogen compounds of tungsten is not feasible as these compounds are not very good conductors.

Little is known about the electrolysis of aqueous and non-aqueous solutions of tungstates. Smith⁷ observed that no effect is produced by the electrolysis of neutral solutions of tungstates, but that in acid solutions a blue color and a blue precipitate (presumably W_2O_5) is produced. The blue compound changes to brown as the current is allowed to run for some time. When the compound is exposed to the air after electrolysis, the brown changes back to blue.

The author does not agree entirely with Smith. He not only obtained the blue and brown compounds described by Smith, by the electrolysis of sodium tungstate acidified with H_2SO_4 , but he also obtained a blue solution and a blue precipitate which turned to brown by the electrolysis of sodium tungstate in a neutral solution. The conditions, however, were somewhat different. Smith used platinum electrodes, while the author used tungsten electrodes.

Leiser⁸ electrolyzed an acid solution of sodium tungstate between a nickel anode and a platinum cathode, and obtained a blue precipitate which when analyzed was found to be W_2O_5 . With a lead cathode he obtained a brown deposit which probably was WO_3 .

Rosenheim⁹ electrolyzed a solution of H_2WO_4 in an alcoholic solution of HCl (gas). H_2WO_4 dissolves in this solution to the extent of 9.8 per cent H_2WO_4 . He used graphite as anode material. With a platinum cathode the reduction proceeded only as far as penta-valent tungsten (W^{V}). With mercury or cadmium cathodes, the reduction varied with the current density, while with zinc cathodes, the reduction proceeds to tetra valent tungsten (W^{IV}). Rosenheim obtained a series of oxides of tungsten varying in valence from five to two. He obtained no metallic tungsten.

Up to this date, 1909, no satisfactory method had been developed for the electrolytic deposition of tungsten and no metallic tungsten had been obtained.

In June, 1910, a patent¹⁰ was issued in Germany for the electrolytic deposition of metallic tungsten from an aqueous or organic solution of pertungstic acid, H_2WO_6 , or one of its salts.

In the same month of the same year, a second patent¹¹ was issued to the Wolfram-Lampen A.G. for the electrolytic deposition of tungsten from organic solutions of WCl_6 .

Fischer¹² tried to deposit metallic tungsten from solutions of WCl_6 in absolute ethyl alcohol saturated with HCl (gas) and from solutions of WCl_6 in glycerine. With the latter the concentration of the dissolved WCl_6 was too small for practical observations. Fischer used carbon as anode and platinum as cathode in his work. With a low concentration of WCl_6 (3 gm/150 c.c. of alcohol), he obtained a green solution, the green color being due to a reduction to penta valent tungsten. He¹³ found this green color to be due to a triethoxyl substitution product of tungsten pentachloride, $WCl_5(OCH_3)_3$.

With a higher concentration (22 grams of WCl_6 per 120 c.c. of alcohol) he obtained, on the cathode, a black precipitate which could not be strictly called tungsten metal. He decided that it was WO_3 .

Fischer tried also to obtain tungsten by the method described by other German patents¹⁴ but without success. He obtained by the electrolysis of pertungstic acid, a blue-black precipitate, which when analyzed showed 92.33 per cent tungsten. This corresponds to WO_3 .

It seems, in going over the literature, that although some of the earlier investigators thought that they had produced metallic tungsten by electrolysis, in nearly every case the precipitate obtained was some tungsten

*A paper presented at the New York Meeting of the American Electrochemical Society on September 8, 1916.

¹ See p. 47 for all references.

compound, principally WO and perhaps a lower oxide. Fischer tried to verify the claims made by the German patents, but he obtained no pure metal.

The work on the electrolytic behavior of tungsten which the author here presents in a preliminary report, was divided into four sub-heads.

1. Single potentials E. P. of tungsten:
 - A. E.P. of tungsten in various electrolytes.
 - B. E.P. of tungsten in saturated solutions of tungsten hydroxide in various electrolytes, bearing on the solubility of tungsten oxide.
2. The anodic behavior of tungsten and passivity:
 - A. In acids, and in neutral salt solutions in water.
 - B. In acids, and in neutral salt solutions in organic solvents.
 - C. In inorganic and organic alkalies with a bearing on the electrolytic recovery of tungsten.
3. A. The use of tungsten in a voltaic cell.
B. The use of tungsten in a standard cell.
C. The use of tungsten in a storage cell.
4. The author has reserved all observations made on the electrolytic deposition of tungsten for future publication.

Single Potentials of Tungsten

The single potential measurements were made in order to obtain some light on the relative solubility of tungsten in solutions of various electrolytes.

Insoluble electrodes give single potentials of the positive and negative ions in solution. In a 1/1 n. NaOH solution we should get, if the anode were insoluble, the value of the oxygen electrode, 1.47 V (H = O). The single potential for tungsten in 1/1 n. NaOH solution is -0.316 V (H = O), a value very much smaller than the oxygen potential. It follows, then, that the tungsten anode goes into solution in NaOH and ionizes. The rate of solution varies with the solvent used.

Three half cells were used as auxiliary electrodes in measuring the single potentials. The first, the normal KCl-calomel half cell, was used with acid and salt solutions. The second, a half cell made from Hg, red HgO and 1/1 n NaOH was used with alkali solutions. The third, a half cell made from Ag, Ag₂O and 1/1 n NaOH was used as a check on the other two cells.

The 1/1 n KCl-calomel electrode was made according to standard specifications.¹⁸ The single potential of this electrode was taken as +0.56 volts. The potential of the second cell, made with the same construction as the first, but having HgO substituted for HgCl, and 1/1 n NaOH substituted for KCl, was taken as +0.445 volt¹⁹. The third cell, made from Ag, Ag₂O and 1/1 n NaOH was taken as +0.655 volt²⁰. The cells were checked up against each other and found to agree within amounts not greater than those allowed for experimental error.

In the combination,

the emf. obtained was 0.1588 volt with the mercury in the calomel, positive. If the single potential of the calomel electrode is +0.56 and that of the mercury oxide electrode is +0.445 V., the emf. produced by the combination, neglecting the liquid potential KCl | NaOH should be +0.115 volt. Since we get an emf. of 0.1588 volt, we conclude that the liquid potential KCl | NaOH is +0.0438 volt.

Similarly with the combination,

(the silver being positive) we get an emf. of +0.0488 volt. The value of the liquid potential KCl | NaOH is calculated to be in this case +0.0462 volt.

$$+0.655 + x + (-0.56) = 0.0488$$

$$x = -0.0462$$

$$x = \text{NaOH} | \text{KCl} = -0.0462$$

then $-x = \text{KCl} | \text{NaOH} = +0.0462$.

Finally in the combination,

with silver positive, the emf. obtained was 0.209 volt. This checks up with 0.210 volt = [+0.655 + (-0.445)].

The tungsten electrodes used in these measurements were 75 mm. long and 3.2 mm. in diameter. They were made from a high-grade tungstic acid which was reduced to tungsten metal by hydrogen. The metal powder was pressed into a rod at a high pressure and melted electrically in hydrogen. After cooling in the same gas, the rod was hot swaged to size, cut in half, and two electrodes of the same composition obtained.

Before making the choice of this form of tungsten metal, we made several single potential measurements with different kinds of so-called tungsten metal, made by different processes. It was found that the potential of these various metals in 1/1 n NaOH varied within wide limits. A black finely divided metal powder had a single potential of -0.704 volt (H = O), while gray compact melted rod had a single potential (E.P.) of -0.316 volt (H = O). See Table I.

Upon closer and further observations we concluded that the finely divided black metal contained a lower form of oxide, either as a mechanical mixture, or adsorbed to, and covering the metal particles. The high E.P. in this case is not the W | NaOH potential, but the E.P. of W₂O₃ | NaOH. Tungsten oxides are more soluble in NaOH than W and have higher E.P.'s in NaOH than tungsten.

Following is a table showing the emf.'s as measured with the Hg | HgO | NaOH electrode, of various forms of tungsten metal. The E.P.'s are expressed in terms of calomel = O, calomel = +0.56 and hydrogen = O.

TABLE I

1	2	3	4	5
Form of Metal	EMF.	E.P. Cal=0	E.P. H=0	E.P. Cal=+0.56
	Volts	Volts	Volts	Volts
Black powder	+0.872	-0.987	-0.704	-0.427
Gray powder	+0.776	-0.891	-0.608	-0.331
At. Wt. powder	+0.657	-0.882	-0.499	-0.222
Rod No. 1	+0.873	-0.988	-0.405	-0.128
Rod No. 2	+0.561	-0.676	-0.393	-0.116
Rod No. 3	+0.494	-0.609	-0.326	-0.049
At. Wt. rod	+0.484	-0.599	-0.316	-0.039

Column 2 in Table I gives the emf. values as actually measured. They may also be taken as E.P.'s of NaOH | W when the value of the auxiliary electrode is taken as zero. The E. P.'s of W | NaOH would be the same values numerically, but opposite in sign.

It was suggested, at the International Congress of Berlin²¹, that in all cases the directly measured values be given and that the 1/1 n KCl calomel or the Nernst hydrogen electrodes be employed as auxiliary electrodes and taken as zero. These direct measurements may be taken as the E.P.'s of the combinations referred to the calomel or hydrogen electrodes as zero. (Cal = O) (H = O). Since we used the HgO half cell (already described) as the auxiliary electrode, it is necessary to calculate to the calomel values. The relation of calomel to mercury oxide is,

$$\text{E.P. Cal} = \text{HgO} + 0.115 \text{ volt.}$$

It follows that in order to change the HgO values to calomel values, it is only necessary to add 0.115 volt to the emf. readings and change the signs to reduce these to W | NaOH. These E. P.'s are shown in column 3.

A relation also exists between the E.P. of the hydrogen electrode and that of the calomel electrode. This relation²² is expressed by

$$\text{EP}_H = \text{EP}_{cal} + 0.283 \text{ volt.}$$

Column 4 gives the E.P.'s of W | NaOH compared to H = O.

Column 5 gives the values in terms of Cal = +0.56 volt.

The emf.s' given in Table I and the following tables were obtained by means of a Wolff potentiometer connected, with a standard Weston element, to a small storage cell to furnish current and a D'Arsonval galvanometer. After compensating the standard Weston element and the storage cell, the potentiometer was adjusted to zero swing on the galvanometer. The emf. was read directly from the potentiometer.

The customary precautions were taken in connecting up the cells to prevent the different electrolytes from mixing. Glass U tubes 80 mm. long and 2 mm. bore through which clean cotton cord was passed, served to connect one electrolyte with another. In some cases, a cup containing the same electrolyte as the one in which the tungsten was immersed, was interposed between the latter and the cup containing the second electrolyte. This was to further reduce the contamination of the first electrolyte with the second.

Table II gives the results obtained with W in the various electrolytes used.

In Table II, column 1 gives the 1/1 n acid solutions in which the tungsten rod was immersed. Column 2 gives the emf.s' measured with the calomel electrode as an auxiliary electrode. Column 3 shows the calculated

KCl	+0.280	+0.280	0.000	+0.280	+0.280	+0.563
KNO ₃	+0.017	+0.593	-0.0037	+0.513	+0.017	+0.390

E.P.'s of W | sol compared to calomel = +0.56 volt, disregarding liquid potential KCl | acid sol. Column 4 gives the E.P.'s KCl | acid sol. calculated from Planck's

formula $\left[EP = 1.99 \times 10^{-4} T \log \left(\frac{U_1 + V_2}{U_2 + V_1} \right) \right]$. Column

5 shows the E.P.'s W | sol. corrected for liquid potential KCl | acid sol. (calomel = +0.56 volt). Column 6 gives the E.P.'s for W | sol. compared to calomel = 0 not corrected for liquid potentials, while column 7 gives the E.P.'s for W | sol. cal = 0 corrected for E.P.'s KCl | acid sol. Column 8 gives the E.P.'s for W | sol. compared to H = O.

Table III gives the same results for bases as Table II gives for acid. In this case the auxiliary electrode Hg | HgO | NaOH = +0.445 volt was used. Column 5 gives the E.P. W | sol. compared to HgO = +0.445. These values are identical to E.P. W | sol. compared to cal. = +0.56. From these figures the E.P. W | sol. values compared to cal. = 0 are obtained and given in column 6. The E.P.'s W | sol. H = 0 are shown in column 7.

Tables III-b and III-c are practically the same except that in the former case we used the silver oxide electrode, while in the latter we used the calomel electrode. Table IV gives the results obtained with 1/1 n solution of the halogen salts of K, and table V, the results obtained with K salts of the acids shown in Table II.

It is seen from Table II that the E.P. W | 1/1 n acid sol. varies with the acid used, and that it is highest with HNO₃ and lowest with H₂SO₄. Tables III-a, III-b, and III-c show that with KOH and NaOH the E.P.'s are practically the same, while with NH₄OH the E.P. is lower numerically and higher algebraically than those of NaOH or KOH. The E.P. of W | KCN is much higher numerically (and lower algebraically) than any of the others. Tables IV and V show the E.P. for W | sol. in the various salts.

The potential of tungsten in 1/1 n HNO₃ may be compared to the potential of copper in 1/1 n (ion concentration) CuCl₂ solution. The E.P. of Cu | CuCl₂ is -0.329 volt (H = O)², while that of As | AsCl₃ is +0.293 volt (H = O).

The potential of W in the alkalis may be compared in the same way, that of W in KCN being higher than that of iron but lower than that of nickel; the potential of W in NaOH, KOH and NH₄OH being higher than that of thallium, but lower than that of tin. In like manner the potentials of W in the halogen and other

salts can be compared with the potentials of other metals.

We have arranged a relative potential table in order of increasing E.P. algebraically from the lowest algebraic value to the highest algebraic value. See Table VI. In column 2 are given the E.P.'s of W | sol. calculated from the measurements taken. Column 3 gives the E.P.'s for Fe, Ni, Tl, etc., taken from Le Blanc.

It was not possible to determine the E.P. of tungsten in aqueous solutions of its salts, because the salts of tungsten, *e.g.*, the hexachloride and hexabromide, are readily decomposed by water. Fischer²² and others have found that WCl₆ dissolves very readily in many organic solvents without decomposition, and that some of the solutions are quite conducting. Fischer chose, as a specific solvent, absolute ethyl alcohol, and measured the E.P. of W | WCl₆ in solutions of varying concentrations of WCl₆, using, as an auxiliary electrode, a calomel half cell, the electrolyte of which was a saturated solution of lithium chloride in alcohol. He found that a 0.102 n (molecular) solution of WCl₆ produced, along with the auxiliary half cell, an emf. of 0.465 volt, the tungsten being positive. From this value he calculated the E.P. of W | 1/1 n (ionic) sol. WCl₆ to be 0.680* volt (H = O). He also calculated the E. P. H₂O — C₂H₅OH to be 0.071 volt. He assumes that

and substituting the values obtained above he gets

$\text{EP W} - \text{WCl}_6(\text{H}_2\text{O}) = 0.609 \text{ volt}^* (\text{H} = \text{O})$
a hypothetical value. He decides that W lies between Sb and Hg in the electrochemical series given by Le Blanc.

Analogous to Fischer's experiments, we thought it possible to find the E.P. of W in saturated solutions of W(OH)₆ in 1/1 n HCl, H₂SO₄, and HNO₃, and from the E.P.'s obtained to calculate the E.P.'s in 1/1 n (ionic) solution of W(OH)₆. The solutions of W(OH)₆ were prepared by electrolyzing the solvents between tungsten electrodes until a copious excess of yellow precipitate was obtained. The anode during electrolysis in each case went through a series of color changes from brown through blue to yellow, after which tungstic acid was precipitated from the solution. These color changes will be discussed later. We considered the solvents saturated with W(OH)₆ when the precipitate began to form. The reactions which take place at the anode during electrolysis produce a hydroxide of tungsten, which dissolves to saturation and ionizes. When the solvent is saturated with ions, the molecular W(OH)₆ being un-

stable, breaks down to H₂WO₄ and analogous compounds by the loss of water. The reactions expressing these changes being,

The end product, anhydrous WO₃, is probably never reached in this case.

Analogous reactions occur between ionic chlorine and tungsten. Tungsten hexachloride forms and dissolves. Being unstable in water, it immediately decomposes to W(OH)₆.

W(OH)₆ dissolves to saturation and the excess breaks down to WO₃ in the same manner as in the above case. In case either Cl ions or OH ions are discharged at the anode, the end products will be the same. Analogous reactions occur in HNO₃ and H₂SO₄ solutions.

That W and Cl ions do unite to form WCl₆ has been shown by electrolyzing a saturated solution of HCl (gas) in absolute ethyl alcohol between tungsten electrodes which have been separated by a porous cup. The anode solution becomes colored yellow by the dissolved WCl₆ that has been formed.

Our emf. measurements, Table IX, have shown that W(OH)₆ is not only soluble in 1/1 n HCl, H₂SO₄, and HNO₃, but also that the W(OH)₆ is ionized to W ions and OH ions. It is dissolved as a true solution and not a colloidal solution, though some colloidal tungstic acid may be present in the solution. Unless the W(OH)₆ were ionized, no emf. would have been obtained in the combination,

We have assumed that the dissolved tungsten is present as a hydroxide, W(OH)₆, and that this hydroxide ionizes to W ions and OH ions in the same manner that Pb(OH)₂ ionizes to Pb ions and OH ions in the lead accumulator.²³⁻²⁴ According to Dolezalak,²⁴ PbO₂ hydrolyzes to Pb(OH)₄, which ionizes to a tetravalent lead ion and four OH ions.

If W(OH)₆ is an amphoteric electrolyte,²⁵ the tungsten in solution must migrate as cations to the cathode in acid solution, and as anions to the anions in alkaline solution.²⁶

From direct measurements, the combination

gave an emf. of +0.117 volt with the tungsten in the W(OH)₆ as positive. This shows that the half cell W | W(OH)₆ is 0.117 volt more positive than the half

H₂SO₄ cell in which there is no W(OH)₆ in solution. The combination is a concentration cell, the right-hand member being the more dilute with respect to W(OH)₆.

According to Nernst,²⁷ the dilute solution always presents the sign of the more rapidly moving ion. It is obvious that the mobility of the OH ion is much greater than that of the W ion. The more dilute solution will then be negative to the more concentrated with respect to W(OH)₆. The concentration of the H and the SO₄ ions are approximately the same in both half cells.

If instead of having W(OH)₆ in solution, we had paratungstic acid, H₂W₂O₇, or ortho tungstic acid, H₂WO₄, we would have WO₃ ions and an increased number of H ions in the right-hand half cell (assuming H₂WO₄ dissolved). Since the H ion is more mobile than the WO₃ ion, the more dilute solution would then be positive. Experiment showed, however, that the more dilute solution is negative, taking the sign of the more mobile of the ions resulting from the dissociation of

*Fisher has confused his signs in his calculations.

the $W(OH)_6$. Tungsten must then exist as the cation in solution, and the solution must contain $W(OH)_6$.

Tables VII, VIII and IX give the results of the experiment.

+W HCl / HCl W- $W(OH)_6$	+0.037 volts
+W HNO_3 / HNO_3 W- $W(OH)_6$	+0.009 volts

In Table VII the E.P.'s of W in N acid sol. are shown. Table VIII shows the E.P.'s of W in N acid solutions saturated with $W(OH)_6$. Table IX shows the order of solubility of $W(OH)_6$ in the three acids. It is least soluble in HNO_3 and most soluble in H_2SO_4 . In each of the three cases the e.m.f. is the result of the difference of concentrations in the two members of the cell. The concentrations of $W(OH)_6$ in the right hand members are very small. We determined the amount of $W(OH)_6$ that is dissolved in the three 1/1 N acid solutions to saturation by evaporating a large volume of the solution to dryness, igniting and weighing as WO_3 . We find

0.02281 gm. WO_3 [= 0.02816 gm. $W(OH)_6$]
per 1000 c.c. n n H_2SO_4
0.01067 gm. WO_3 [= 0.01315 gm. $W(OH)_6$]
per 1000 c.c. n n HCl
0.00025 gm. WO_3 [= 0.00030 gm. $W(OH)_6$]
per 1000 c.c. n n HNO_3

If we try to calculate the concentration of the $W(OH)_6$ solution by means of the modified Nernst formula

$$EP = \frac{0.058}{V} \log \left(\frac{C_1}{C_2} \right)$$

Where C_1 and C_2 are the ionic concentration, we run into difficulties. We cannot calculate the concentration of $W(OH)_6$ from conductivity measurements because the conductivity of the 1/1 n acid solutions are so high and the concentration of the $W(OH)_6$ is so low that the increase in conductivity due to $W(OH)_6$ would not be much greater than a value due to experimental error.

From the values of concentration found by evaporating to dryness, we can calculate the E.P. for W | 1/1 n $W(OH)_6$.

$$EP_n = EP - \frac{0.058}{v} \log c$$

This was found to be +0.336 volt in n H_2SO_4 , +0.342 volt in n HCl and 0.358 volt in n HNO_3 .

Anodic Behavior of Tungsten in Electrolytes

Le Blanc²⁸ studied the anodic behavior of tungsten in various electrolytes, and found that in 1/1 n solutions of H_2SO_4 , HCl and HNO_3 the metal becomes passive. In KOH, NH_4OH , NaOH, however, he found that the metal stays active within wide ranges of current density. If, however, the current density reaches or exceeds a maximum in alkaline solutions, tungsten becomes passive. Interrupting the current for a short time destroys the passivity.

From experiments which we have made, we have noticed that when 1/1 n solution of HCl, H_2SO_4 , HNO_3 , KF, KCl, KBr, KI, K_2SO_4 , and KNO_3 are electrolyzed between tungsten electrodes separated by a porous cell, the anode always becomes coated with a series of films ranging in color from brown through purple, dark blues, light blues, greens, to yellow. The color changes are independent of the nature of the anions and cations in the solution used, but are dependent upon the current density and the time of electrolysis.

With an initial current density of approximately 0.00025 ampere per square dm., the color changes of the film on the anode can be very easily followed. I use the term initial current density to denote the current at the start. As the electrolysis proceeds, the resistance of the film increases and the current flowing is decreased. The first flash of brown color is quite marked and the change from brown to purple is also quite marked. The change to dark blue and to light blues is slower, and it is difficult to tell when the greens stop and the yellow begins. The change from green to yellow is gradual. These changes are a function of current density and time. Tables XI, XII, XIII give some comparative figures on three runs which we made with a 1/1 n solution of KCl.

If the initial current density be increased to 2 amp. per dm², the anode assumes a yellow color almost immediately. The eye, not being quick enough to follow the color change from brown to yellow, sees only the yellow.

Rosenheim obtained a similar series of colored oxides in reversed order by the cathodic reduction of H_2WO_4 . He started with yellow and ended with brown WO_3 . Our results are analogous to his in that we have the same series of colors formed electrolytically, but differ from his results in that we have anodic oxidation and Rosenheim had cathodic reduction.

In the literature we find mention made of many tungsten oxides. Some of these are:

WO	Black ²⁹
WO_2	Brown ³⁰
W_2O_5	Blue ³¹
W_2O_{11}	Blue ³²
W_2O_{11}	Green Blue ³³
WO_3	Yellow ³⁴

Mixtures of these oxides produce intermediate colors. Brown and blue give purple; blue and yellow give green. These colors agree with the colors obtained by the anodic oxidation of tungsten.

It is obvious that the degree of passivity depends on the nature of the oxide film which covers the tungsten. The brown oxide is less noble than the blue or the yellow.

When the current density is very low, and the volume of electrolyte is very large, and the diffusion comparatively rapid, no passivity was observed and no colored films were formed until the electrolyte had become saturated with $\text{W}(\text{OH})_6$. Passivity in this case is accompanied by a cloudy precipitate. Passivity is a function of the volume of electrolyte used and the rate at which the anode products are dissolved. The solubility of the anode films was shown by allowing a "passified" anode, which had been thoroughly washed with distilled water after electrolysis, to stand in fresh unused portions of the same electrolyte in which it had been made passive for an hour or two. The time depended on the electrolyte.

A sample of "passified" tungsten became "active" by allowing to stand over night in a tightly sealed bottle of freshly distilled water. Solution of NaOH, KOH, NH_4OH , etc., make "passive" tungsten "active" almost instantly. The passivity of tungsten is due to a film of adherent oxide or hydrated oxide, and is a function of the rate R at which the film is produced, and the rate R_1 at which the film is dissolved into the solution used to produce it. If $R = R_1$ we have equilibrium, while if $R > R_1$ the metal becomes passive.

We have found that tungsten dissolves anodically in aqueous solution of NaOH and KOH with the formation of the respective ortho tungstates.

Passivity occurs only when the current density is so high that the rate of formation of $\text{W}(\text{OH})_6$ is faster than the rate of solution and diffusion in NaOH.

We have found that tungsten dissolves anodically in a solution of HCl (gas) in absolute ethyl alcohol without becoming passive and without the liberation of gas. The anode solution becomes yellow, due to the dissolved WCl_6 , and the cathode solution becomes green, due to reduction.³⁵

We have found that tungsten dissolves anodically in NH_4OH , NH_2OH , the four methyl ammonium hydroxides, the four ethyl ammonium hydroxides, and propyl ammonium hydroxides within wide limits of current density without becoming passive. The first product of the reaction, $\text{W}(\text{OH})_6$, dissolves on the electrolyte to form salts.

Ekeley³⁶ has found that $\text{H}_2\text{W}_2\text{O}_7$ dissolves in amines

to form salts which are analogous to $(\text{NH}_4)_6\text{W}_2\text{O}_{24}$. As an example:

$\text{H}_2\text{W}_2\text{O}_7$ with $\text{C}_2\text{H}_5\text{NH}_2\text{OH}$ forms $(\text{C}_2\text{H}_5\text{NH}_4)_6\text{W}_2\text{O}_{24} \cdot 5\text{H}_2\text{O}$. His analysis of the salts conforms with his formulae.

Electrolyzing $\text{C}_2\text{H}_5\text{NH}_2\text{OH}$ between tungsten anodes produces $(\text{C}_2\text{H}_5\text{NH}_4)_6\text{W}_2\text{O}_{24} \cdot 5\text{H}_2\text{O}$. Analogous salts are obtained with

$\text{CH}_3\text{NH}_2\text{OH}$; $(\text{CH}_3)_2\text{NH}_2\text{OH}$; $(\text{CH}_3)_3\text{NHOH}$; $(\text{CH}_3)_4\text{NOH}$
 $(\text{C}_2\text{H}_5)_2\text{NH}_2\text{OH}$; $(\text{C}_2\text{H}_5)_3\text{NHOH}$; $(\text{C}_2\text{H}_5)_4\text{NOH}$
 $(\text{CH}_3)_3\text{NH}_2\text{OH}$; $(\text{CH}_3)_2\text{N}_2\text{HOH}$, etc.

In NH_4OH tungsten dissolves anodically with a valence of 6 and 100 per cent efficiency to produce ammonium paratungstate $(\text{NH}_4)_6\text{W}_2\text{O}_{24}$. NH_4Cl was added to increase the conductivity of the solution. In conjunction with this experiment, we determined, from the loss in weight of the anode, the electrochemical equivalent of tungsten and found that when the metal dissolves with a valence of 6 the value of the electrochemical equivalent was 0.3173 mg. per coulomb. The theoretical value calculated from the formula

$$E_{100} = \frac{\text{At Wt}}{\text{Valence} \times 96580} = \frac{184}{6 \times 96580}$$

is 0.3175 mg. per coulomb³⁷.

We have found that tungsten also dissolves anodically in NH_4OH . We have not determined the salt formed, but it is probably analogous to ammonium paratungstate.

The anodic behavior of tungsten in aliphatic substitution products of NH_4OH , and the aromatic hydroxyl compounds and substitution products will be discussed in a future paper.

The Use of Tungsten in Cells

Fink³⁸ mentions the use of tungsten in cells in a paper on "The Applications of Ductile Tungsten," and promises good results both in voltaic and in standard cells. We have since made a further study of these two types of cells and taken up the application of W to storage cells.

VOLTAIC CELLS

If W is to be used as anode in a voltaic cell, it is desirable to use an electrolyte in which both the tungsten and the anodic-reaction products are most soluble. Barring KCN, tungsten is most soluble in solutions of KOH or NaOH. The E.P. W | sol. will be algebraically lowest (or in commoner terms the highest — value) in NaOH solutions³⁹. In addition to the anode, it is desirable to have as a cathode, a metal, the E.P. of which is a high + value in the same electrolyte (if possible). Hg and Ag are two such metals.

Mercury has an E.P. in a saturated solution of HgO in 1/1 n. NaOH of +0.445 volt⁴⁰ compared to calomen = +0.56, or —0.115 compared to cal. = O, or +0.168 volt compared to H = O. Silver in a saturated solution of Ag_2O in 1/1 n. NaOH has an E.P. of +0.655 volt⁴¹ when cal. = +0.56, or +0.378 when H = O. The E.P. W | NaOH = —0.039 when cal. = +0.56, or —0.316 when H = O.

The emf. of the combinations

Hg | HgO | NaOH || NaOH | W
 and Ag | Ag_2O | NaOH || NaOH | W

will then be respectively

$$(+0.445) + (-0.039) = 0.484 \text{ volt}^{42}$$

$$(+0.655) + (-0.039) = 0.694 \text{ volt}^{43}$$

The mercury and silver are both positive to the tungsten.

To increase the emf. of the cell it is only necessary to increase the concentration of the NaOH solution.

TABLE XIV

Normality of NaOH	E.M.F. Fused W.	Powdered W.
	Volts	Volts

The results are very promising with tungsten, both as fused slugs and as metal powder. In our preliminary tests the metal powder has given higher emf. values than the fused metal.

Following are readings taken on a small experimental cell. The voltage was read across the electrodes of the cell. Resistance was put in series with the cell and the ammeter.

Volts	Ampe.
1.05	Open

0.05	0.1000
0.01	0.1020

Other cells in which W enters either as metal or compound are being studied.

STANDARD CELLS

In connection with the use of tungsten in standard cells we have made the following observations:

TABLE XV

1 Electrodes	2 E.M.F.	3 E.P. Sol ¹ Metal HgO = +0.445
Sat. Na ₂ W ₂ O ₇ /Hg ₂ W ₂ O ₇ /Hg	-0.401 Volts	-0.846 volts
Sat. Na ₂ W ₂ O ₇ /Cu ₂ W ₂ O ₇ /Cu	-0.235	-0.690
Sat. Na ₂ W ₂ O ₇ /W	+0.152	-0.297
Sat. Na ₂ W ₂ O ₇ /Zn ₂ W ₂ O ₇ /Zn	+0.302	-0.143
Sat. Na ₂ W ₂ O ₇ /Cd ₂ W ₂ O ₇ /Cd	+0.583	+0.138

Single potential measured with auxiliary electrode Hg | HgO | NaOH = +0.445 volt.

Combining these single electrodes one with another we obtained the combinations which gave the emfs. as shown in Table XVI.

The emf.'s of the combinations check up very well with the theoretical emf.'s calculated from the E.P.'s of the single electrodes, Table XV.

These cells are still under investigation and further reports on tests made on their temperature coefficients, life and stability will be given.

TUNGSTEN STORAGE BATTERY

At present we have under investigation several cells made with combinations of tungsten and tungsten oxides.

These cells, A, B, C (Table XVII), were made with tungsten and tungstic acid. The three combinations are shown in the table. Cell A had tungsten and tungstic acid as the positive electrode and tungsten metal

TABLE XVI

+	Hg	Hg ₂ W ₂ O ₇	Na ₂ W ₂ O ₇ sat.	Na ₂ W ₂ O ₇ sat.	W	= +0.552 volts
+	Cu	Cu ₂ W ₂ O ₇	Na ₂ W ₂ O ₇ sat.	Na ₂ W ₂ O ₇ sat.	W	= +0.395
-	Zn	Zn ₂ W ₂ O ₇	Na ₂ W ₂ O ₇ sat.	Na ₂ W ₂ O ₇ sat.	W	= +0.154 volts
-	Cd	Cd ₂ W ₂ O ₇	Na ₂ W ₂ O ₇ sat.	Na ₂ W ₂ O ₇ sat.	W	= +0.434

+	Hg	Hg ₂ W ₂ O ₇	Na ₂ W ₂ O ₇ sat.	Na ₂ W ₂ O ₇ sat.	Zn ₂ W ₂ O ₇	Zn = +0.703
+	Hg	Hg ₂ W ₂ O ₇	Na ₂ W ₂ O ₇ sat.	Na ₂ W ₂ O ₇ sat.	Cu ₂ W ₂ O ₇	Cu = +0.131
+	Cu	Cu ₂ W ₂ O ₇	Na ₂ W ₂ O ₇ sat.	Na ₂ W ₂ O ₇ sat.	Cd ₂ W ₂ O ₇	Cd = +0.831 volts
+	Cu	Cu ₂ W ₂ O ₇	Na ₂ W ₂ O ₇ sat.	Na ₂ W ₂ O ₇ sat.	Zn ₂ W ₂ O ₇	Zn = +0.537
+	Zn	Zn ₂ W ₂ O ₇	Na ₂ W ₂ O ₇ sat.	Na ₂ W ₂ O ₇ sat.	Cd ₂ W ₂ O ₇	Cd = +0.283

as the negative before charging. Cell B had tungsten and tungstic acid as both electrodes, while cell C had tungsten-tungstic acid as negative electrode and tungsten as positive, being the reverse of A, before charging. The cells were connected in series and charged. The emf. of each cell was measured immediately after charging and found to be 3.00 volts for cell A, 3.20 volts for cell B, and 6.20 volts for cell C. Twenty-four hours after charging the cells, the emf.'s had dropped to 0.2 volt, 0.55 volt and 0.85 volt respectively. The cell C having W | WO₃ as positive electrode and W | WO₃ as negative electrode has so far been the most satisfactory.

TABLE XVII—BEFORE CHARGING

Type	Positive Electrode	Negative Electrode	E.M.F.

C	Brown W WO ₃ · yH ₂ O	Blue W WO ₃ · xH ₂ O	+6.20	+0.85

The results obtained with tungsten storage cells are very promising and will be discussed more fully in a more detailed paper which will follow.

Summary

1. A brief review of the literature is given.
2. The single potentials of tungsten in n/n solutions of acids, alkalies and neutral salts were calculated from e.m.f. measurements.

From emf. measurements and calculated E.P. we have found that:

3. Tungsten has a lower potential in $n, 1$ alkalis than in $n, 1$ acids and a lower potential in $n, 1$ acids than in $n, 1$ solutions of neutral salts.

4. Tungsten has a lower potential in $n, 1$ KCN solutions than in $n, 1$ solutions of KOH (or NaOH) and a lower potential in the latter than in a $n, 1$ NH_4OH solution. The potential in $n, 1$ KOH (or NaOH) corresponds to that of thallium in a thallium chloride solution containing $n, 1$ TI ions.

5. Tungsten has a lower potential in $n, 1$ H_2SO_4 than in $n, 1$ HCl , and a lower potential in the latter than in $n, 1$ HNO_3 . The potential of W in HNO_3 corresponds to that of Cu in a CuCl_2 solution containing $n, 1$ Cu ions.

6. The order of potential of W in $n, 1$ solutions of neutral salts is as follows: KNO_3 , KF , KBr , KCl , K_2SO_4 , KI , the potential being highest in solutions of KI .

7. It is shown that in solutions of tungsten in acids, tungsten occurs as cation, whereas in alkaline solutions tungsten occurs in the anion.

8. Tungstic acid is more soluble in $n, 1$ H_2SO_4 than in $n, 1$ HCl and more soluble in $n, 1$ HNO_3 . Direct chemical tests confirm this.

9. Tungstic acid hydrolyzes and goes into solution as $\text{W}(\text{OH})_6$ in $n, 1$ solution of H_2SO_4 , HCl , HNO_3 . W appears in the cation.

10. $\text{W}(\text{OH})_6$ in water is an electrolyte and not a colloid.

11. Tungsten dissolves anodically in aqueous and non-aqueous solutions of alkalis, acids and salts.

12. Tungsten anodes become passive in aqueous and non-aqueous solutions of alkalis, acids and salts.

13. Tungsten becomes passive in aqueous solution of alkalis and organic solutions of alkalis, acids and salts only at very high current densities.

14. Tungsten becomes passive in aqueous solutions of acids and salts even at low current densities. It stays active in these solutions only at very low current densities.

15. The passivity of tungsten is due to adherent films of hydrated tungsten oxides. The films may be readily dissolved and the passivity of the metal thereby destroyed.

16. The hydrated oxide films appearing on the anode vary in color from brown, thru blue to yellow. The degree of passivity varies with the color of the film.

17. The passivity phenomena observed can be readily interpreted by the oxide theories of passivity.

18. The electrochemical equivalent of tungsten was found to be .3173 mg. per coulomb. This corresponds very closely with the theoretical.

19. Experiments on the use of tungsten in voltaic, standard and storage cells are recorded. The phenomena observed in connection with the storage cell are of particular interest. The potential difference between brown oxide (positive) and blue oxide (negative) is $+0.75 \text{ V}$.

This work was carried out in the research laboratory of the Edison Lamp Works, Harrison, N. J., under the direction of Dr. C. G. Fink.

Stability of Paraffin Hydrocarbons

By Gustav Egloff and Robert J. Moore

(Contribution from the Havemeyer Chemical Laboratory, Columbia University No. 291.)

In current opinion there exists a belief in regard to paraffin hydrocarbon stability that has become almost axiomatic, namely, that with increase in the boiling point and greater complexity of the molecule, hydrocarbons are the more readily decomposed, either into their ultimate products or into intermediate compounds. It is the aim of this research to show that such a belief is untenable.

A statement such as the following, "It is well known that the simpler petroleum hydrocarbons are stable at much higher temperatures than those of higher molecular weight," is met with time and again, but no specific references to experiments which verify it can be found. This opinion seems to have originated from the results of simple atmospheric distillation of crude petroleum where cracking has been noted at approximately 200 deg. C. and upward,¹ after the lower-boiling-point paraffins have been distilled off. But the latter have not been subjected to the higher temperatures. If now we take these low-boiling-point paraffin hydrocarbons, and also those boiling at 200 deg. C. and upward, and subject them to a higher temperature, say 700 deg. C., their true relative stability could then be determined. This is essentially the scope of the following investigation.

It will be shown experimentally that stability is not a direct function of the complexity of the paraffin chain molecule, but that if stability is graphed against the boiling points of the paraffins there results a curve having the maximum stability at about 250 deg. C. representing the compounds ($\text{C}_{12}\text{H}_{26}$ to $\text{C}_{14}\text{H}_{30}$), minima at the lowest boiling points (C_2H_6 to C_4H_{10}) and the highest boiling points ($\text{C}_{20}\text{H}_{42}$ to $\text{C}_{22}\text{H}_{46}$). The above compounds have been isolated from a Pennsylvania paraffin base petroleum oil.² Stability will be given in

terms of per cent, specific gravity and refractive index of the recovered oils, and in the distillation analysis and aromatic formation in the recovered oils, compared with the original fractions, per cent to carbon and gas; and volume of gas formed.

General Procedure

A Pennsylvania paraffin base crude oil was fractionated in cuts to 150 deg. C., 150-200 deg., 200-250 deg., and above 250 deg. C. under vacuum into cuts of 50 deg. each. The residue, a semi-solid, was discarded. After the specific gravity, index of refraction, per cents of unsaturated and nitratable hydrocarbons were determined, each fraction was then subjected to a temperature of 700 deg. C. in an electrically heated furnace by passing the oil through at the rate of 200 c.c. per hour. The volume of gas formed was taken and its unsaturation and hydrogen content determined. The recovered oils were measured and analyzed as follows: distillation, specific gravity, refractive index, unsaturateds, and benzene, toluene and xylene content.

Specific gravities were taken with the Westphal balance at 15.5 deg. C., and where amounts were small with a 1 c.c. capacity pycnometer. A Pulfrich refractometer was used for index of refraction values. Unsaturation and nitrative methods of procedure have been previously published.¹

The distillation was conducted by means of a Glinzky distilling head and the fractions made after several redistillations according to a method previously described.² The cut to 95 deg. C. represented the benzene fraction, 95 to 120 deg. C. the toluene fraction, and from 120 to 150 deg. C. the xylene fraction.

Analysis of Starting Oil.

The Pennsylvania petroleum crude oil was distilled by means of a 3 liter Engler distillation flask in two 1800 c.c. portions in fractions up to 150 deg., 150 to 200 deg. C., 200 to 250 deg. C., and in vacuum at 150 deg. to 200 deg. C., and from 200 deg. to 250 deg. C. Distillation in vacuum was carried on, due to cracking taking place at 250 deg. C. and atmospheric pressure. These fractions for simplicity's sake will be called subsequently fractions A, B, C, D, E.

TABLE 1—ANALYSIS PETROLEUM CRUDE OIL

Temperature, Deg. C.	A	B.	C.	D.	E.
of Fractions to 150	150-200	200-250	150-200, 200-250,	200-250,	
Per cent by volume.....	18.8	15.5	13.1	13.3	12.1
Specific gravity.....	0.724	0.763	0.786	0.811	0.833
Refractive index.....	1.40156	1.42271	1.43507	1.44773	1.45872
Per cent unsaturated 1.5	2.5	1.0	1.5	0.5	
Per cent nitratable hydrocarbons	3.0	7.0	1.5	5.5	4.5

FURNACE USED

The furnace used for the following work was electrically heated over a length of 18 in., and has been described in detail elsewhere.⁴

DETAILS OF THERMOLIZATION

For each run 300 c.c. of the oil were passed at the rate of 200 c.c. per hour in the cracking zone. The temperature of this area was kept constant at 700 deg. C. within + or - 5 deg. C. The temperature was recorded by means of a base-metal thermocouple calibrated against a platinum-iridium standard. The condenser was surrounded with ice and the recovered oil collected in a receiver, while the gas passed through a standard referee wet meter and collected directly into a Hempel burette for analysis. The volume registered

on the meter in cubic feet was converted to liters by the factor 28.315. The gas was analyzed for unsaturated hydrocarbons by fuming H_2SO_4 , which although it is known to absorb a certain per cent of the higher paraffins⁵ was nevertheless sufficiently accurate for this work.

The hydrogen content of the gas was determined by means of Jaeger's fractional combustion method modified by Whitaker and Leslie.⁶ A discussion of this method has been made by Burrell and Oberfell,⁷ and also by Porter and Taylor.¹⁰

A. The Percentage, Specific Gravity and Refractive Index of the Recovered Oils

TABLE 2

Temperature, Deg. C.	A	B.	C.	D.	E.
of Fractions to 150	150-200	200-250	150-200, 200-250,	200-250,	
Per cent recovered oil by volume.....	2.3	29.3	66.7	25.0	20.0
Specific gravity.....	0.777	0.790	0.794	0.858	0.953
Refractive index.....	1.43663	1.44076	1.44206	1.46486	1.49428

The stability of the hydrocarbons present in the fractions at 700 deg. C. increased as the boiling points increased, reaching a maximum in the cut 200 to 250 deg. C. and then decreased. The least stable of the hydrocarbons were those boiling to 150 deg. C., which contained mainly the paraffin hydrocarbons pentanes to nonanes.

The percentage yield of the recovered oils from the thermolized fractions indicates quite clearly the gradient of the stability of the starting, mainly paraffin hydrocarbons. The paraffins apparently reached a maximum stability under the conditions of the experiment in the cut of 200 to 250 deg. C., and then decreased in the higher boiling point fractions. This fact is brought out quite forcibly when one takes the values of the percentage of the starting fractions decomposing to form gas and carbon (Table 3).

TABLE 3—THE PERCENTAGE OF STARTING FRACTIONS DECOMPOSED TO FORM CARBON AND GAS

Temperature, Deg. C.	A	B.	C.	D.	E.
Per cent to carbon and gas.....	97.7	70.7	33.3	75.0	80.0

The maximum of 97.7 per cent occurs in the lowest boiling point paraffin hydrocarbon fraction and reaching a minimum of 33.3 per cent in fraction C, while a maximum is also shown in fraction E of 80 per cent. The most stable paraffins are those somewhat midway between the two extreme boiling point paraffin hydrocarbons.

The specific gravity of the recovered oils increases from the lowest to the highest boiling point fraction, although not markedly higher than the values of the starting fractions, except the fraction boiling in vacuum between 200 and 250 deg. C. Table 4 tabulates the two sets of values:

TABLE 4

Temperature, Deg. C.	A	B.	C.	D.	E.
of Fractions to 150	150-200	200-250	150-200, 200-250,	200-250,	
Sp. gr., original fraction.....	0.724	0.763	0.786	0.811	0.833
Sp. gr., thermolized fractions	0.777	0.790	0.794	0.858	0.953

In each case the thermolized oil shows a higher specific gravity value, which is to be expected as apparently in all thermal decomposition work of paraffin hydro-

⁶Worstall, *J. A. C. S.* 21, 245, 1899.

⁷Orndorff and Young, *Am. Chem. J.* 15, 249, 1893.

⁸Burrell and Seibert, *Bull. Bureau of Mines*, 42, 45, 1913.

⁹Jour. Ind. Eng. Chem. 8, 634, 1916.

¹⁰Jour. Ind. Eng. Chem. 8, 228, 1916.

¹¹Proc. Am. Gas Inst. 9, 255, 1914.

¹²J. Ind. Eng. Chem. 6, 845, 1914.

carbons, aromatic compounds are formed, and these have a higher specific gravity than the paraffins, as shown by averaging those boiling within the limits:

	Average Spec. Gravity Paraffin Hydrocarbons	Spec. Grav. Aromatics
Benzene cut 0° to 95° C.	0.720	0.881
Toluene cut 95° to 120° C.	0.730	0.871
Xylene cut 120° to 150° C.	0.760	0.869

Since the specific gravity of hydrocarbons is an additive property, the physical constant of a thermolized oil would show an increase over the starting paraffin hydrocarbons whenever aromatic compounds were formed.

The specific gravity of the fraction 200 to 250 deg. C. shows the least change in value due to thermolization, which in turn checks up the high per cent of recovery of the starting fraction, and the low per cent decomposing to form carbon and gas.

The refractive index values of the recovered oils increased as the boiling points of the fractions, viz., showing the same tendency as the specific gravity values. A comparison of the refractive index values of the thermolized with the original fractions is shown in Table 5.

Temperature, Deg. C.	A	B	C	D	E
of the Fractions	to 150	150-200	200-250	150-200, 200-250,	200-250,
Refractive index original fractions	1.40156	1.42271	1.43507	1.44773	1.45872
Refractive index thermolized fractions	1.43663	1.44076	1.44206	1.46486	1.49428

The physical constant of refractive index in each case shows a higher value of the fractions after thermolization. Similarly to specific gravity, refractive index is an additive value for hydrocarbons, and will likewise note *percentage* aromatics when present in an oil, due to their higher value when compared to paraffins. A comparison of the refractive indices of paraffin and aromatic hydrocarbons within a similar boiling point range shows the wide difference in the values in the following table:

	Boiling Point Range	Average Refractive Indexes
Paraffins	68 to 174° C.	1.403
Aromatics	80.4 to 167° C.	1.501

The least change in the refractive index value of the thermolized oils occurred in the fraction 200-250 deg. C., where the least thermal decomposition took place under the conditions of the experiment.

TABLE 6. DIFFERENCES IN THE SPECIFIC GRAVITIES AND REFRACTIVE INDEX OF THE ORIGINAL AND THE THERMOLIZED FRACTIONS

Temperature, Deg.	A	B	C	D	E
to 150	150-200	200-250	150-200, 200-250	200-250	Vacuum
Spec. Gravity	0.053	0.027	0.008	0.047	0.120
Refractive Index	0.03507	0.01805	0.00699	0.01713	0.03556

The evidence as to the changes taking place in the original fractions after thermolization is nowhere brought out more clearly than by taking the differences in the specific gravity and refractive index values between the starting and the recovered oils. The values for the specific gravity and refractive index show a minima in both cases in the fraction from 200 to 250 deg.

The specific gravity in fraction C shows a difference of 0.008 in the recovered oil and 0.00699 for the refractive index, which indicates a relatively small change in the composition of the recovered oil from the starting fraction. These two sets of values bring out forcibly the greater stability of the paraffin hydrocarbons (C_6H_6 to $C_{12}H_{22}$) under the conditions of the experiment of 700 deg. C. and rate of oil flow of 200 c.c. per hour, than those boiling below and above this fraction.

B. The liters of gas per liter of oil used, the percentage of unsaturateds and hydrogen in the gas

	TABLE 7	A	B	C	D	E
Temperature, Deg. C.	of the fractions	to 150	150-200	200-250	150-200, 200-250, Vacuum	200-250, Vacuum
Liters of gas per liter of oil used	710.2	560.7	420.4	476.7	514.4	
Percentage unsaturateds	16.1	39.9	40.0	40.6	42.2	
Percentage hydrogen	40.2	24.0	20.5	15.2	13.5	

The liters of gas per liter of oil used decreased to a minimum at the fraction 200-250 deg. C. The maxima were found to be at the lowest and highest fractions. The fraction boiling to 150 deg. C. gave 710.2 liters of gas composed of hydrocarbons and hydrogen. This value is in accord with the other data, indicating the low stability of paraffin hydrocarbons boiling to 150 deg. C. in comparison to the higher boiling point fractions. The minimum of 420.4 liters occurred in the fraction 200-250 deg. C., where the least decomposition of the starting oil took place.

The analysis of the gas samples resulting from the thermal decomposition of the fractions gave an increasing percentage yield of the unsaturateds with a rise in the boiling point of the fractions. The percentage yield of unsaturateds increased from 16.1 to 42.2 in the highest fraction. In the last four fractions only a 2.3 per cent difference of the unsaturateds was noted and three of the values are almost identical.

The hydrogen content of the gas decreased rapidly from 40.2 per cent to 13.5. The maximum hydrogen percentage occurred in the fraction boiling to 150 deg. C., while the minimum occurred at the highest boiling point fraction. As the ultimate products of all thermal decomposition of hydrocarbons are hydrogen and carbon, it is significant as indicating the stability of low boiling point hydrocarbons at elevated temperatures,¹¹ when the percentage yield of the starting 150 deg. C. fraction is 2.3 per cent and the gas analysis 40.2 per cent hydrogen—that in reality they are much less stable at 700 deg. C. than the higher boiling point paraffin hydrocarbons.

C. The distillation analyses of the recovered oils

In the introduction it was stated that one object of this investigation was to show that one of the current hypothesis of paraffin hydrocarbon stability is not tenable, namely, that the higher the boiling point and more complex the molecule, the more readily is it broken up, either into its ultimate products or into intermediate compounds of widely different character. The proof of this untenableness is offered by various experimental results. But of no small value to this end are the distillation figures of the recovered oils, from which some interesting relations may be drawn.

	TABLE 8. DISTILLATION ANALYSIS OF RECOVERED OIL	A	B	C	D	E
Temperature, Deg.	to 150	150-200	200-250	150-200, 200-250, Vacuum	200-250, Vacuum	
To 95	7.0	2.4	1.0	8.8	16.6	
95-120	18.0	8.9	2.6	2.8	10.0	
120-150	35.5	29.4	5.0	2.6	11.1	
150-175	15.3	24.8	15.4	4.0	0.5	
175-200	..	16.5	8.7	2.6	0.8	
200-225	..	10.0	31.5	6.5	2.5	
225-250	..	5.2	19.8	20.0	5.2	
250-275	..	..	8.3	22.9	5.9	

Since our starting oils were mainly pure paraffins whose boiling points ranged from 150 deg. for A to 350 deg. for E, we should expect (if the breaking down of the hydrocarbon is a direct function of the complexity of its molecule) that the distillation fraction to, say, 95 deg. C. of each oil could be expressed graphically in a straight line. That is, that a larger percentage to 95 deg. C. was recovered with increasing boiling point

¹¹Egloff, Met. and Chem. Eng., 16, 692, 1916.

of the starting oil. But such is not the case. The distillation figures for the 95 deg. C. cut show a minima for oil C (B.P. 200-250), the percentages being as follows: 7.0, 2.4, 1.0, 8.8, 16.6 from oils A to E. Fraction 95 deg. to 120 deg. C., which shows the largest boiling point distinction from these higher boiling point originals, also shows a minimum for the oil C. Since the five oils were run under exactly similar conditions, there seems to be no doubt but that these parallel tendencies values, high at each end and lowest at oil C, betoken a characteristic of the latter oil to greater stability under heat. The same conclusion will be arrived at subsequently from other considerations.

D. The Specific Gravity of the Distillation Cuts of the Recovered Oil

TABLE 9

Temperature, Deg.	A.	B.	C.	D.	E.
C	to 150	150-200	200-250	150-200, Vacuum	200-250, Vacuum
To 95	0.790	0.800	0.823	0.874	0.859
95-120	0.744	0.790	0.822	0.873	0.875
120-150	0.761	0.770	0.798	0.865	0.879
150-175	0.767	0.773	0.775	0.861	0.860
175-200	0.780	0.791	0.783	0.851	0.850
200-225	0.790	0.803	0.789	0.842	0.858
225-250	0.796	0.810	0.798	0.836	0.954
250-275	..	..	0.811	0.838	0.967

The specific gravity values of the distillation cuts increased in general with increase of the boiling points of the starting fractions in the cuts to 95 deg. C., 95-120 deg. and 120-150 deg. C. In the distillation cuts above 150 deg. C. the minimum specific gravity values are found to be in fraction C, the mid-boiling point starting oil.

E. The Refractive Index of the Distillation Cuts of the Recovered Oils

TABLE 10

Temperature, Deg.	A.	B.	C.	D.	E.
C	to 150	150-200	200-250	150-200, Vacuum	200-250, Vacuum
To 95	1.42645	1.43431	1.46334	1.49245	1.48870
95-120	1.42534	1.44237	1.46298	1.49246	1.49488
120-150	1.42645	1.42927	1.44600	1.49060	1.50875
150-175	1.43985	1.43038	1.43269	1.48825	1.52998
175-200	1.44880	1.44136	1.43401	1.47713	1.53559
200-225	1.44990	1.45041	1.43683	1.47274	1.54886
225-250	..	1.46288	1.44166	1.46912	1.55088
250-275	..	..	1.44791	1.46585	1.56239

The refractive indices follow somewhat the same trend as the specific gravity values, and simply reinforce the evidence provided by the other physical constants used in these experiments.

F. The percent of unsaturated hydrocarbons in the distillation cuts of the recovered oils

TABLE 11

Temperature, Deg.	A.	B.	C.	D.	E.
C	to 150	150-200	200-250	150-200, Vacuum	200-250, Vacuum
To 95	18.0	5.5	25.0	12.5	17.5
95-120	13.0	10.0	22.0	20.0	25.0
120-150	12.0	5.0	7.5	13.0	20.0
150-175	11.5	5.0	2.5	16.0	23.0
175-200	..	6.0	2.5	9.5	15.0
200-225	..	12.5	5.0	2.5 (Naphthalene present)	..
225-250	..	19.0	2.0	7.5	..

No specific regularity in the percentage of unsaturated hydrocarbons in the various distillation cuts is to be noted. The bulk of the unsaturated hydrocarbon formation has taken place in the three cuts to 150 deg. C. The maximum formation of unsaturates occurred in fraction C in cuts to 95 deg. C., 95-120 deg. C., and 120-150 deg. C., indicating that this particular fraction formed the amylenes, hexylenes, and heptylenes to decylenes most readily. Fractions C, D and E formed upon thermalization unsaturated hydrocarbons in much higher percentage yields than the low boiling point fractions A and B. The percentage of unsaturates in

the gas with the exception of fraction A gave only a 2.3 per cent difference in the other four fractions—ranging around 40 per cent in value while fraction A gave 16.1 per cent of unsaturated hydrocarbons. Since the percentage of hydrogen decreased in fraction A from 40.2 to 13.5 in fraction E, and the unsaturates increased from A to B in the gas, and showed higher values in the distillation cuts in fractions C, D and E in comparison to A and B, with a maximum in the distillation cuts of fraction C, we have two added angles from which to judge the stability of the hydrocarbon fractions started with, that the most stable paraffin hydrocarbons under the conditions of the experiments are those boiling between 200 and 250 deg. C. having formulas from $C_{12}H_{24}$ to $C_{15}H_{32}$.

G. The percentage yield of the aromatics—benzene, toluene and xylene in the recovered oils

TABLE 12

Temperature, Deg. C.	A	B.	C.	D.	E.
of Fractions	to 150	150-200	200-250	150-200, Vacuum	200-250, Vacuum
Per cent by volume					
benzene	3.1	1.2	0.8	8.4	14.4
Toluene	1.3	3.8	1.0	2.8	10.0
Xylene	2.2	2.7	2.0	2.5	11.1

In the recovered oils the yields of benzene ranged from 0.8 to 14.4 per cent. The maximas occurred in the low and high boiling fractions and the minimum in the middle fraction. The toluene percentage ranged between 1.3 and 10, while xylene gave values from 2.2 to 11.1.

The formation of aromatic hydrocarbons is apparently independent of the paraffin hydrocarbons started with. Whether the paraffins are short chained with few isomers or long chained compounds with many isomers, they all apparently decompose, forming the ethylene series, smaller molecular weight paraffin and aromatic hydrocarbons.¹²

H. The percentage yield of the aromatics—benzene, toluene and xylene on the basis of oil used for production

TABLE 13

Temperature, Deg. C.	A	B.	C.	D.	E.
of fractions	to 150	150-200	200-250	150-200, Vacuum	200-250, Vacuum
Per cent by volume					
benzene	0.07	0.4	0.6	2.1	2.9
Toluene	0.02	1.1	1.1	0.7	2.0
Xylene	0.05	0.8	1.1	0.6	2.2

The percentage yields of the aromatic hydrocarbons, benzene, toluene and xylene, on the basis of oil used, emphasizes again the importance of the starting hydrocarbon oil in their production. There is, as illustrated by the above table, an increase from 0.07 to 2.9 per cent in the benzene yield, toluene varies between 0.02 and 2 per cent, and xylene between 0.05 to 2.2 per cent. These values are widely different and show that groups of the high boiling point paraffin hydrocarbons in the distillation cuts lend themselves more readily to aromatic formation than the low boiling point paraffins. This is directly in accord with theoretical considerations when one considers the long chain aliphatic hydrocarbons, with their many isomers, splitting up into a greater number of the ethylene series hydrocarbons and lower boiling point paraffins.¹³ The ethylene series hydrocarbons polymerize, readily forming naphthenes, which decompose to aromatic hydrocarbons.¹⁴

General Discussion

Hartogh¹⁵ has reported that by refluxing a sulphuric acid washed benzene having a distillation value of 91 per cent boiling below 105 deg. C. and a specific gravity of 0.698, that after several hours the analysis gave a much wider distillation range, and upon sulphuric acid treatment a 10 per cent of unsaturated hydrocarbon test.

Engler and Höfer¹⁶ state that this experiment is open to further verification, for they bring out the points as to how far the oxygen of the air or the catalytic effect of the copper vessel used in the distillation entered into giving the recorded results. Further doubt is thrown upon Hartogh's result by the work of later experimenters, who worked with a heavier Russian benzene of a specific gravity of 0.745 and 98 per cent boiling below 148 deg. C. in one case, and in the other a specific gravity of 0.732 and 95 per cent boiling to 130 deg. C. In both cases no appreciable decomposition of the starting oils was noted.

The criticism of Engler and Höfer is of interest, but even though the air or copper catalysed the reaction so as to give the results recorded by Hartogh of 10 per cent unsaturation after distillation, the results are highly significant. Although the decomposition took place by possible catalysers, the results are important when compared with those of the present communication.

It is certain that the viewpoint of the stability of paraffin hydrocarbons toward heat, decreasing with increasing molecular complexity, is no longer tenable from the experimental evidence presented. It is recognized that the behavior of the gaseous paraffin methane in comparison to the liquid paraffins shows marked stability toward heat. In particular methane persists longest in thermal decomposition of hydrocarbons, and is also the most stable of the paraffin hydrocarbons recorded in the literature.¹⁷

A study of the thermal decomposition of individual paraffin hydrocarbons under like conditions would show methane in all likelihood the most stable, with a decrease in stability as the molecular weight increased, to a minimum, and then a maximum would again be reached in one of the paraffins in the group boiling between 200 deg. and 250 deg. C., $C_{16}H_{34}$ to $C_{18}H_{38}$, with another minimum as the complexity of the molecule increased, and perhaps another maximum in a compound like $C_{20}H_{42}$, with the highest molecular weight paraffin hydrocarbon going to the ultimate products carbon and gas.

As to the theoretical considerations involved in the greater stability of the group of paraffins $C_{16}H_{34}$ to $C_{18}H_{38}$ in comparison to the relatively shorter chained compounds $C_{12}H_{26}$ to $C_{14}H_{30}$ information is lacking as to the heats of combustion, heats of formation, internal pressures and similar constants of the higher paraffin hydrocarbons, which would throw light upon the stability of paraffin hydrocarbons.

Conclusions

1. Five fractions of a paraffin-base petroleum oil with boiling points to 150 deg. C., 150-200 deg. C., 200-250 deg. C., and vacuum distilled from 150-200 deg. C. and

200-250 deg. C., have been thermolized at a temperature of 700 deg. C. with a view toward determining their stability at this temperature.

2. It has been established that the fraction boiling between 200-250 deg. C. paraffins with molecular weights between $C_{16}H_{34}$ and $C_{18}H_{38}$ is most stable under the conditions of the experiment.

3. The percentage of starting fraction recovered; to carbon and gas, differences in the specific gravity and refractive indices, volume of gas, per cent of benzene, toluene and xylene in the recovered oil, experimentally determined that the fraction with boiling point between 200-250 deg. C. are the most stable paraffins at 700 deg. C.

TABULATED EXPERIMENTAL RESULTS

	A	B	C	D	E
Distillation temperature of fractions, to 150°C	150-200	200-250	200-250	150-200 Vacuum	200-250 Vacuum
Per cent of recovered oil	2.3	29.3	66.7	25.0	20.0
Per cent to carbon and gas	97.7	70.7	33.3	75.0	80.0
Differences in specific gravity of original and thermolized fractions	0.053	0.027	0.008	0.047	0.120
Differences in refractive indices of original and thermolized fractions	0.03507	0.01805	0.00699	0.0173	0.03556
Liters of gas per liter of oil used	710.2	560.7	420.4	476.7	514.4
Per cent of benzene in recovered oil	3.1	1.2	0.8	8.4	14.4
Per cent toluene	1.3	3.8	1.0	2.8	10.0
Per cent xylene	2.2	2.7	2.0	2.5	11.1

4. It has been shown experimentally that the general belief, as exemplified by the statement, "It is well known that the simpler petroleum hydrocarbons are stable at much higher temperatures than those of higher molecular weight," is no longer tenable.

Synopsis of Recent Metallurgical and Chemical Literature

Iron and Steel

Influence of the Time of Heating Before Quenching on that Operation.—ALBERT PORTEVIN, in an illustrated article of 52 pages, discusses the above mentioned subject in the January-February number of the *Revue de Métallurgie*, pp. 9 to 63. In the introduction to his paper, Portevin discusses in a general way, the state of cooling, the state of quenching, heating, the duration of constant temperature, the law of cooling and the interpretation of the results obtained. In the latter he states, that from the theoretical point of view, the effect on the electrical resistance must be considered, as, according to Benedicks, it is a means for quantitatively determining the elements in solid solution. Furthermore, from the practical point of view, most of the interest is based on the effects of heating on the mechanical properties of the material treated; and finally, that for all methods of investigation the micrographical study is of paramount importance.

Chapter I treats of the preliminary study of heating in fused salts. The subject is first covered in a general way, then methods for procedure are described, the latter comprising thermometric and calorimetric methods, and finally a study of the various fused salts used is given. The salts tested were potassium nitrate and nitrite, sodium chloride, potassium chloride, fused calcium chloride, hydrated barium chloride, hydrated strontium chloride and pure potassium chloride. The results obtained under varying temperature conditions

are illustrated by numerous curves. Full explanations accompany the curves.

From here on the subject is divided into two parts: First, the effect of the treatment on the mechanical properties and on the electrical resistance of the ordinary carbon steels, and second, the effect of the treatment on special steels. Under the latter head fall tests made on various samples of chromium, tungsten and molybdenum steels. All results, at every instant, are summarized either in tables or curves, or both. Analysis of samples tested are given, and many micro-photographs illustrate the various effects on the structure of the materials tested.

The conclusions drawn from the work are as follows: First, from the practical point of view the rate of transformation in steels is appreciable even at ordinary temperature, and increases with the temperature, and secondly, from the industrial point of view, the properties of a steel depend essentially on the length of time of heating before quenching. These results were obtained after jointly considering the changes in the mechanical properties, changes in electrical resistance, and the change of structure as examined by the microscope.

In an appendix to the same paper the author elaborates on the laws of heating, the calorimetric determination of the total duration of heating of small samples in an industrial gas furnace, the decarbonization of steels in salt baths, and the thermal determination of the intensity of quenching of steels. Like the main article, the appendix is illustrated by curves, tables and micro-photographs.

Copper

The Metallography of Copper.—Under the title, *The Study of Metallography, Internationale Zeitschrift für Metallographie*, VII., 124, 1915, M. V. SCHWARZ treats the metallography of copper. The article is elaborately illustrated and the conclusions drawn by the author are of more than common interest.

Especially of interest are the conclusions drawn on the formation of crystals of copper in the process of electrolysis. The most favorable conditions for the formation of crystals in this process are a low temperature and no agitation of the electrolyte. The cause of the formation of elongated crystals is a lack of diffusion. The disposition of the various crystalline grains may be recognized by the position of the lamellae. The author draws attention to the importance of corrosion figures in the microscopic examination of metals. In a microscopic slide the electrolytic crystals appear more brilliant than the surface of the cut which corresponds most exactly with one of the faces of the crystal.

The author claims to have observed the growth of these electrolytic crystals. He discards the idea of the influence of the grain size on the growth of the crystals, but ascribes the form of the crystal obtained to the aging process. This effect disappears on reheating. The "state of youth" of the crystal, as the author terms it, may be explained by aid of the kinetic theory and the law of mass action.

The elongated crystals form normally on the surface of separation. If, therefore, a copper wire is used as cathode, the crystals appear radially. A cut parallel to the surface of the electrode will then clearly show the copper crystallites. If the conditions of electrolysis are changed during operations, the crystals appear in layers. These layers are successive, but the orientation of the crystals remains unchanged. The electrolytic copper crystals are very susceptible to pressure, so on cutting a sample with a very thin saw one observes before reheating the formation of isolated grains which do not melt in the mass.

Another factor of importance is that the author does not approve of the amorphous theory, as an explanation of what occurs between adjacent crystals. The material between the crystals, according to Schwarz, is made up of crystalline copper, so finely crystallized that the individuals cannot be recognized. This mass he calls "cryptocrystallines." This mass is less stable towards chemical and heat action, than the actual crystals. The polished surface of a sample is explained as the sliding of an upper surface following the sliding surface of the mass proper. The surface on examination shows no tendency whatsoever of forming amorphous material.

Melting Aluminium Chips.—The Bureau of Mines has undertaken an investigation of this subject and published the results in Bulletin 108. The authors are H. W. GILLET and G. M. JAMES. The bulletin gives an account of experiments made to compare the recovery of metallic aluminium in melting down chips such as are obtained in the automobile factories in machining aluminium castings. As aluminium has sold at three times its normal price for the past year, and as a recovery of but 60 per cent of the metal in the chips is common, and a 90 per cent recovery is commercially possible, the preventable loss is of considerable magnitude. The bulletin discusses the causes of the high loss in the usual method of melting chips, and shows that the difficulty of getting the tiny globules of molten metal resulting from the fusion of the very fine chips, to coalesce, when covered with a skin of oxide and dirt, is apparently the main cause for low recoveries.

Two methods of melting can be successfully used to promote coalescence. In one method the chips are kept just above the fusion point and the globules made to coalesce by hand puddling, which breaks through the skin and makes the globules unite. In this method melting is best done in an iron pot heated by oil.

The other is by the use of a flux which dissolves off the skin of dirt and oxide, producing clean globules which can unite. The flux suggested is 85 per cent common salt, 15 per cent fluorspar, used in large amount (20 to 30 per cent of the weight of the chips) and mixed with the chips before charging. Much higher temperatures are required by this method than by the puddling method, so the iron pot furnace is not practicable and melting is best done in graphite crucibles or in a reverberatory furnace. The flux method does not require the constant hand puddling of the other.

Since the presence of dirt and oxide causes low recoveries, the necessity for care and cleanliness in the collection and storage of chips is emphasized. Chips wet with cutting compound will oxidize superficially on storage, but by drying the chips by centrifuging this can be prevented. Perfectly clean chips can be melted without much loss by either method, while very dirty chips cannot be handled by any method so as to give the high recoveries of clean chips, although the two methods mentioned gave better results on dirty chips than any other methods tried. Care and cleanliness in the collection of chips in the machine shop producing them will give chips from which a high percentage of metal can be recovered, with a corresponding increase in the value of the chips sold by the shop. As on an average 15 per cent of the weight of aluminium castings for automobiles is machined off as chips, the possible saving to the automobile manufacturer is much greater than the cost of replacing careful methods for sloppy methods in the collection of chips.

New Paper Process.—According to the Journal of the London Chamber of Commerce, a process for making paper pulp for newsprint out of Kaing grass, which grows wild in Burma, is a success and steps have been taken toward its manufacture.

Recent Chemical and Metallurgical Patents

Various Electric Furnaces

Electric Melting Furnace.—A revolving arc furnace to be used for melting alloys containing zinc, such as the various brasses, and German silver, or containing manganese, such as ferro-manganese, is patented by HORACE W. GILLET and JAMES M. LOHR, of Ithaca, N. Y. The furnace is also adapted to the melting and refining of steel. It is of the indirect arc type, the arc being maintained between the electrodes over the charge (the electrodes being horizontal), but no arc is maintained between the electrodes and the charge. In melting yellow brasses agitation has been found to reduce vaporization losses of zinc on pouring, and agitation is provided for in this furnace by rotation of the furnace. The electrodes revolve with the body of the furnace. (1,201,224-5, Oct. 10, 1916.)

Electric Arc Furnace.—An electric furnace in which it is possible to use either freely burning arcs, that is, arcs burning between the electrodes, or arcs burning between the electrodes and the furnace charge, is patented by CLAS W. HARRY W. ECKERMANN of Ljusne and IVAR RENNERFELT of Djursholm, Sweden. Freely burning arcs are stated to be an advantage when melting scrap and the like, in case the charge is non-conductive when cold, and when the chemical reaction in the charge causes a violent boiling and formation of slag, as when puddling pig iron. Arcs contacting with the charge may be of advantage for deoxidizing and desulphurizing when the charge has become melted and the boiling ceased.

By a suitable arrangement of electrodes and connecting cable switch a double-throw switch it is possible, according to this patent, to have the arcs burning either between the electrodes only or between the electrodes and the charge. The idea is illustrated in Fig. 1, which

FIG. 1.—RENNERFELT ELECTRIC FURNACE WITH CONNECTIONS

shows a twelve-electrode three-phase system. With the switch in the present position the side electrodes are disconnected and the bath serves as a neutral point in a Y-connected system. When the switch is thrown to the left the result is a Y-connected system with the conductor 6 serving as a neutral point and arcs between electrodes only. With the switch thrown to the right the result is the same, but a delta connection results. (1,206,057, Nov. 28, 1916.)

Electric Furnace for Treating Gases.—An electric furnace having a rotating flame for treating gases is patented by IGNACY MOSCICKI of Lemberg, Austria-

Hungary. In electric furnaces in which the flame produced by an alternating current rotates under the influence of a magnetic field the reignition of the flame at the instant of reversal is troublesome and requires a relatively higher voltage. The present design attempts to overcome this difficulty by a specially designed conical shape electrode. The chief claim is:

"An electric furnace for the treatment of gases and vapors, in which furnace a high-tension, alternating-current flame rotates under the influence of a magnetic field of force, said furnace having an outer electrode within which is inclosed the reaction chamber; an inner electrode that projects therinto; a hollow ring which is detachably fastened to the outer electrode so as to be readily exchangeable and is provided with an ignition-edge inclined toward the inner electrode and is arranged for the passage of a cooling medium; the interval between said electrodes measured in the direction of flow of the gases increasing very rapidly; the inner electrode being arranged free to be shifted and to be adjusted relatively to the outer electrode in such manner that the ignition-ring remaining free between the electrodes can be adjusted exactly to the tension of the working current so as to be able first to generate the flame at said ring at every current reversal and then, under the influence of the powerful magnetic field and the great velocity of the gases, to draw the flame out to a great length and absolutely within a small fraction of the period of a single alternation." (1,201,607, Oct. 17, 1916.)

Induction Furnace.—An induction furnace for the melting of metals is patented by JAMES R. WYATT of Philadelphia, Pa., and assigned to the Ajax Metal Company, Inc., of Philadelphia, Pa. Stirring of the molten charge is accomplished by the motor effect of induced currents flowing in opposite direction close together and at an acute angle to each other. For details of the furnace the patent specification should be referred to. (1,201,671, Oct. 17, 1916.)

Nitric Acid

Nitrogen Fixation Furnace.—A new design of electric furnace for nitrogen fixation is patented by ERNEST K. SCOTT of Belvedere, England (assigned to Atmospheric Nitrates, Ltd., of Manchester, England). "The primary object of the invention is to increase the efficiency of such furnaces by insuring that practically all the air which enters the furnace passes through the arc. This object is attained according to this invention by the employment of electrodes so shaped and disposed that they inclose a central space, which is preferably in the form of an inverted cone, arcing gaps being provided between adjacent electrodes." (1,203,276, Oct. 31, 1916.)

Improvements in Birkeland-Eyde Furnace.—A method of bracing the electrodes in an electric arc furnace of the Birkeland-Eyde type is patented by CARL O. A. DÖVLE of Notodden, Norway. In the operation of electric arc furnaces with arcs moving along the electrodes, irregularities have occurred due to vibration. In the present patent these vibrations are eliminated by braces. (1,204,349, Nov. 7, 1916.)

Chemical Engineering

Separation of Oils.—Machine shops and garages accumulate from time to time certain quantities of waste oils and greases which have no commercial value, being mixtures of lubricating oils, burning oils, and gasoline. Mr. SIDNEY CORNELL proposes to separate the gasoline and more volatile oils from the heavier lubricating oils, greases, etc., by the following method: A closed retort is provided with two steam coils in the upper and lower part of the retort respectively so that

the upper and lower parts may be heated independently to desired temperatures. The oil mixture is fed into the retort so as to fill its lower half and is heated by means of the lower steam coil while at the same time saturated steam is blown into the oil mixture from below through a number of jet openings in the bottom of the retort. The steam passing through the oil mixture brings it into an emulsified or frothy condition. When the emulsion or froth comes in contact with the upper steam-heated coil above the liquid, separation of the gasoline, benzine, etc., from the emulsion takes place and these light volatile hydrocarbons, together with the remaining steam, distil over into a condenser, where they are condensed. The heavier lubricating oil remains back as residue in the bottom of the retort. (1,202,969, Oct. 31, 1916). [The process has been in operation in a large-scale experimental plant for some time in Long Island City, where we recently witnessed a successful test on separating gasoline from crude oil. As operated, it appeared that cracking plays a part in the process. It is stated that the process, the patent rights of which have been assigned to Mr. Richard Elkins, will be used in a plant in the Oklahoma oil field by the Intercoast Oil & Refining Company.—Editor.]

Aging Wine.—Dr. ARTHUR LACHMAN of San Francisco, well known by his charming little book on "The Spirit of Organic Chemistry," and equally well known by his more recent successful business activity in wine making, has patented a process for aging wine in which the wine is subjected to heat, pressure, and electric treatment; to save fuel and to make the operation continuous, the heat of the wine whose treatment has been completed is used to warm up the wine which is to be treated. A pressure of 5 to 25 lb. per square inch is satisfactory for sweet wines, with a temperature of 140 deg. Fahr. The electrical treatment consists of the passage of high-tension alternating current between electrodes in the treatment tank. The process produces in twenty-four hours aging results which otherwise require many months. (1,204,669, Nov. 14, 1916.)

Progress in the Use of Kieselguhr in the Insulation of Metallurgical Equipment

We have repeatedly referred in these columns to the very interesting and progressive work of the Kieselguhr Company of America, with principal offices in Los Angeles and New York, and with mines in Santa Barbara County, Cal., in adapting their kieselguhr products, "celite" and "silocel," to the solution of insulating problems for metallurgical equipment. Progress has especially been made in increasing thermal efficiency and producing greater uniformity of temperature, resulting in an increase of works' capacity and of uniformity of grade of product, together with better working conditions.

Hot-Metal Cars.—Recently, silocel insulating brick have been used for the insulation of hot-metal cars and metal mixers, giving a greater radius for these cars and an appreciably reduced loss through the formation of sculls, and almost entirely eliminating the chilling effect due to heat losses while in the car.

A 2-in. layer of silocel insulation as a backing for the refractory lining reduces the external temperature of the car to such an extent that the hand can be held on the outer shell with entire comfort.

Mains and Bustle Pipes.—The effect of insulating high-temperature mains, flues, and bustle pipes is primarily to give a greater capacity to the stove equipment and produce a more uniform blast temperature at the tuyeres. In one of the several installations in which a 4½-in. course of silocel insulating brick are

used as a backing for the lining of bustle pipes the variation in temperature on the far side of the bustle pipe was reduced by more than 50 deg., with a notable increase in the uniformity of the pig produced.

In the operation of waste-heat boilers the flue insulation is of vital importance.

Hot-Blast Stoves.—One of the most serious heat losses occurring in blast-furnace equipment is that through the sides and tops of hot-blast stoves. This effect, of course, is particularly noticeable in the cold weather, which, in certain cases, causes a complete shutdown of the stack, due to inability to obtain the proper blast temperature at the tuyeres. Within the past two years more than sixty hot-blast stoves have been completely insulated in sides and top with silocel products, many of which are now operating under unusually high thermal efficiency.

Crucible Furnaces.—One of the primary considerations in the operating of crucible furnaces is the difficulty in handling high temperatures encountered in this work. In the insulation, for instance, of the back of a crucible furnace with 2½ or 4 in. of insulation, a comfortable working condition is produced for the men, and at the same time it gives an appreciably more uniform furnace than can be obtained in any other manner. A number of crucible-steel furnaces have been insulated with both silocel insulating brick and powder, and are operating under unusually successful conditions.

This same factor, of course, applies to handling case-hardening and tempering furnaces, the majority of which are being insulated with silocel products.

Regenerators.—The insulation of regenerator and checkerwork settings for open-hearth furnaces, and other forms of equipment requiring pre-heated gases, produces increased thermal capacity and a higher average blast temperature, because of the elimination of the valleys and the peaks necessary to take care of the conduction losses in uninsulated equipment. In other words, the working temperature of the blast as it leaves the regenerator is more nearly a straight line in the case of insulated equipment than is possible in the ordinary form of regenerator, in which the heat losses by conduction are allowed to go on unchecked.

Insulation of Foundations.—Heretofore, little or no attempt has been made to check the heat losses from the bases and foundations of high-temperature equipment, although this has been found to be one of the most serious losses. This has been due to the effect that insulating materials of the proper structural strength have not been generally available for this character of work. With the introduction of silocel products, with very high insulating value combined with mechanical strength, this difficulty has been largely overcome, and many of the largest installations of heated equipment in the country are now having their bases, as well as the exposed parts entirely insulated.

By-product Coke Ovens.—The uniformity of interior temperature is of primary importance in the production of coke, either in by-product, beehive or gas generators, and, while the method of applying insulation varies in the different types of equipment, on account of the mechanical construction and the arrangement of the condensing equipment, the effect of insulation is to a large extent comparable to that in other forms of high-temperature equipment.

Gas Plants.—The modern coal-gas plant is now entirely insulated from the base to the top, especially the retorts, to give a higher yield of gas, more uniform operating temperatures, and a more uniform grade of coke than has been possible in the older types of equipment. Several of the largest plants in the country are

now completely insulated with silolac products and are producing at an unusually high thermal efficiency.

Oil Stills.—The application of insulation to the settings and mains in oil stills is rather recent, and the effect is very pronounced in the saving of fuel, etc.

The Critical Point in the Heat Treatment of Steel

In the heat treatment of steel it is all-important to know exactly when the critical temperature or the "critical point" is reached. In the "crit-point," a new instrument of the Gibb Instrument Company of Pittsburgh, Pa., use is made of the well-known fact that steel in the process of heating loses its magnetic properties when it is brought to its critical point. Through the medium of electromagnetic coils the magnetic condition of the steel in the furnace is determined. A magnetic indicator is placed in the circuit, so that

this meter immediately indicates whether the steel has reached its critical point. When the surface of the steel in time becomes non-magnetic, or in other words, the temperature of the surface comes up to the critical point, the meter needle approaches the red line indicative of the critical point and gradually comes nearer and nearer to it, as the heat penetrates the steel and the interior is brought to the critical point.

It will be seen that the "crit-point" does not measure temperature. But the exact knowledge of the temperature is irrelevant as long as the heat-treating man has a simple and exact means off hand for ascertaining when the critical temperature is reached.

Tests on a Die-Casting Copper Alloy

The following tests were made on samples of "Ampco" bronze, a 90 per cent copper-base alloy made by the American Metal Products Company of Milwaukee, Wis.

The name bronze is somewhat of a misnomer, as the alloy contains no zinc, tin, lead or phosphorus. It was developed to furnish a low-melting-point copper-base alloy for die casting which should have great strength. It is furnished in grades having a tensile strength of from 50,000 to 100,000 lb. per square inch elastic limit, 20,000 to 45,000, elongation 50 per cent to 4 per cent, reduction of area 28 per cent to 8 per cent and Brinell hardness 70 to 280.

New York Meeting of American Institute of Chemical Engineers

The winter meeting of the American Institute of Chemical Engineers will be held in New York City from Wednesday to Saturday, Jan. 10 to 13, 1917. All the business meetings and technical sessions will be held at the Chemists' Club. Excursions (for members only) have been arranged for the afternoon of Wednesday, the whole of Thursday, and the afternoon of Friday. A subscription dinner will be held on Thursday.

The following papers will be presented:

Wednesday, 11 a. m.:

- "Unpreparedness," President George D. Rosengarten.
- "Recent Developments in Chemical Engineering Equipment," H. D. Miles, president Buffalo Foundry & Machine Company.
- "Corrosion of Ingot Iron, Containing Cobalt, Nickel, or Copper," Prof. Herbert T. Kalmus and K. B. Blake, Queens University.

Wednesday, 8 p. m.:

- "The Human Side of the Development of Chemical Industries," G. W. Thompson, National Lead Co.
- "The Fixation of Nitrogen," Prof. John E. Bucher, Brown University.

Friday, 10 a. m.:

- "The Decatur Sewage Disposal Plant of the Electrolytic Sanitation Company," William Hoskins, Mariner & Hoskins.
- "The Effect of Centrifugal Force on Colloidal Solutions," E. E. Ayres, Jr., Sharples Specialty Co.
- "Recent Developments in the Absorption and Distillation of Volatile Liquids," Charles L. Campbell, E. B. Badger & Sons Company.

Friday, 8 p. m.:

- "Chemical Engineering Aspects of Renovating a Sulphide Mill," Hugh K. Moore, Berlin Mills Company.
- "Recovery of Benzol from Coke Oven and Illuminating Gas," C. J. Ramsburg, H. Koppers Company.

Personal

Dr. William Beckers of the Beckers Aniline and Chemical Co., Brooklyn, N. Y., addressed the American Association of Woolen and Worsted Manufacturers at its recent eleventh annual meeting in New York. The title of his paper was "Dyestuffs Progress in America and What Is to Be Expected in the Future; the Relation of the Manufacturer of Explosives to the Manufacture of Dyestuffs."

Mr. George A. Burrell, consulting chemist, Pittsburgh, Pa., lectured before the Franklin Institute of Philadelphia, Pa., on December 7th, on the technology of the natural gas gasoline industry.

Mr. Meyer Davis, formerly chief engineer, has been appointed manager of the San Francisco office of the Asbestos Protected Metal Company. The office is in the Hobart Building.

Mr. J. V. N. Dorr was presented with the John Scott Legacy Medal by the city of Philadelphia on the recommendation of the Franklin Institute, for his inventions along the line of metallurgical apparatus.

Dr. Sam Eyde, the well known joint inventor with Prof. Birkeland, of the nitrogen fixation process which is now operating successfully in Norway, passed the half century mark recently. The Scandinavian papers have given a summary of Dr. Eyde's accomplishments, and foremost of these is his active and successful work developing the nitrogen fixation industry in Norway. Three hundred thousand horsepower are operating at Rjukan on this industry alone and the net income of the company, of which Mr. Eyde is manager, was in the year of 1913, 25,000,000 kroner, or close to \$9,000,000. At the present time the daily production of this plant is five hundred tons of nitrates. Mr. Eyde made several large donations for various scientific and humanitarian purposes in commemoration of his anniversary.

Mr. Edwin Higgins has been elected as consulting engineer of the United States Bureau of Mines.

Mr. Theodore J. Hoover has opened an office in San Francisco in the Mills' building.

Mr. J. E. Johnson, Jr., consulting engineer of New York City, sailed on December 15 for China on professional business.

Mr. Frederick Laist is the new manager of the Washoe Reduction Works at Anaconda, Montana, in which capacity he succeeds E. P. Mathewson. C. A. Lemmer has been appointed assistant manager.

Mr. G. A. Marsh, superintendent of the Pueblo smelter of the A. S. & R. Co., was in Denver recently, on business.

Mr. Wm. Motherwell, flotation engineer, has returned to Nelson, B. C., and has entered consulting practice. Mr. Motherwell's experience began ten years ago at Broken Hill, Australia, and since that time he has had experience in Queensland, Arizona, Colorado and Mexico.

Professor W. A. Noyes, director of the chemical laboratory of the University of Illinois, will lecture on "the electron theory" before the Franklin Institute as part of the 1916-1917 program.

Mr. Raymond B. Price, vice-president of the United States Rubber Company recently returned to New York from a three months' trip to Europe. He was entertained at luncheon at the Technology Club on December 15, after which he gave a very interesting talk on recent developments in Europe as affecting American business now and after the war. He said that production has been speeded up enormously on all sides in Europe, and the lessons they have learned in efficiency in centralized control and in the rela-

tions between labor and capital are not going to be lost after the war but will be retained and utilized in industry.

Mr. A. K. Richards is now engineer and superintendent of construction of the Colorado Portland Cement Co. He was formerly with the American Vanadium Co., Mackintosh-Hemphill & Co., of Pittsburgh, and the Cambria Steel Co., Johnstown, Pa.

Mr. Charles H. Rosenthal, formerly with the Calco Chemical Company of Philadelphia is now chemist with the Benzol Products Company at Marcus Hook, Pa.

Mr. R. W. Schultz, who represents the Minerals Separation Company, Ltd., is at Houghton, Mich.

Mr. Joseph Stabel, of Buffalo, has been elected a director of the Inspiration Gold Mines, Ltd., Mr. Stabel has purchased a large interest in the company.

The Chemical Market in the United States in 1916

Coal Tar Products

Production during the year just closed of coal-tar crudes and intermediates has perhaps increased generally in greater proportion than any other department of the chemical industry. The vast work started in the early part of 1915 was successfully and on a broader scale carried on during 1916. Manufacturers of derivatives or coal-tar intermediates have increased in number and during the year practically all intermediates formerly produced in Germany and Switzerland were turned out here in varying quantities and with varying success. The result naturally has been a lowering of market values.

Broadly, these new companies have followed two widely diversified methods of operation. A majority has seemingly lacked the effort of concentration, with the result that a long line of intermediates were produced that as a rule lacked the proper degree of quality. These firms undermined their financial standing, with the result that a number of them passed out of existence, changed ownership or produced a line that promised a larger return. Capital generally was not lacking. The chief difficulties appear to have been the employment of inefficient talent, and the characteristically American effort to turn out a maximum amount in a minimum period resulting in an over-production, mainly of faulty products. New plants were, as a rule, hastily constructed. Apparatus manufacturers beset with raw material problems could not make timely deliveries. The cost of production was difficult to ascertain, and even at the date of writing intermediates are being sold at widely varying figures, reflecting the inability of some manufacturers to arrive at an accurate basis of their overhead.

On the other hand, there have been a number of manufacturers who have concentrated on a small line with the object of improving quality and disregarding quantity. These firms have without exception prospered. Their initial outputs perhaps were far from the standard established by the Germans, but with persistent effort continued improvement has been noted and to-day the American products rank with any produced abroad.

COAL-TAR CRUDES

The production of benzol has increased remarkably during 1916, and it is estimated that the total output is now no less than 30,000,000 gal. The number of American coke by-product plants with benzol recovery apparatus is sixty-one. The output for the most part has been absorbed by both manufacturers of intermediates

for dyes and for use in explosives. Exports during the early part of the year, particularly to England, were heavy, though within recent months buying by foreign countries has to an extent been curtailed, with the inevitable result that prices have been subject to a downward tendency. Benzol has now reached the average spot price of 57c. to 60c. per gallon, depending on quantity and individual view. This is a decline of 20c. to 23c. for the year. Contract business is to be had at from 54c. to 55c. However, most of the important producers have sold up a considerable portion of their output and are not now gunning for business.

Toluol has slowly but steadily declined from the high level of \$4.80 to \$5 a gallon, which prices were in evidence in the early spring of 1916, to the now prevailing price of \$1.80 to \$2 per gallon for immediate delivery and \$1.60 to \$1.75 for contracts covering delivery next year. On recent government business one large producer quoted \$1.50, and it is known that contracts have been awarded at somewhat less than this figure. The fact that one of the large producers under German ownership has refused to sell a product that would ultimately be used in manufacturing munitions for the Allies has caused a slightly more favorable market for domestic use than for export. Even at the present prices, however, a large margin of profit is shown the manufacturers. The 1916 production is estimated at 8,000,000 gal.

Xylol.—Commercial distilling 90 per cent at 160 deg. has remained comparatively steady at 35c. to 40c., though somewhat keener competition has induced manufacturers to modify their price levels somewhat. The output is small. Spot pure is quoted at \$1.20 to \$1.25; on contract \$1.

Naphthaline has been subject to considerable fluctuation, and from the high level of 17c. to 18c. that was paid for the prime white refined flakes late last winter, the low levels of 6½c. to 7c. were reached during the late summer and fall. Following the import duty of 15 per cent advalorem and 2c. per pound specific imposed recently on imported goods, the local market has strengthened considerably, and domestic manufacturers are quoting from 9c. to 10c., with the English goods held generally at from 10½c. to 11c. There are large surplus stocks available in England, but comparatively small quantities are now reaching this country. The United States production in 1916 is placed at 12,500 tons of refined.

Phenol has had an interesting history during the year, and price changes until recently have been frequent. So great was the demand both from abroad and for domestic account, for use in the manufacture of disinfectants, intermediates for dyes and for explosives, especially picric acid, that nearly twenty new plants started in operation. The increased output, however, combined with a curtailing of the wild demand, was instrumental in bringing prices to lower levels, and several of the new plants went out of existence. The present prices of from 53c. to 55c. show a moderately good profit, considering the cost of raw materials, and with some of the new manufacturers out of the market and a steady volume of demand in evidence, the market shows considerable steadiness, and not a few of the important producers have sold well up on contract. So far thirty-five plants have been equipped with phenol apparatus in this country. One of the operating companies' plant was disposed of at a receiver's sale and has been junked.

INTERMEDIATES

A short summary of the developments of the intermediates is extremely interesting. Chief among the benzol products is *aniline oil*. With the heavy produc-

tion of benzol at the outset of the year, and the big demand for dyestuffs and munitions, the output of aniline was greatly accelerated. Production, however, became excessive and a rapid and steady decline in prices was the attendant result. The average cost of manufacture, as computed by important manufacturers based on prevailing price of benzol and nitric acid, is from 26c. to 30c., and with the present price down to the low levels of from 23c. to 22c. of approximately 35 plants operating at the beginning of the year, all but 15 of them have been closed, and not a few have gone out of business altogether. The present price of aniline oil represents a decline of about 75c. for the 12 months, the year having opened at \$1. Definite figures of the American production of aniline oil are not available, but it is estimated that a year's output is now approximately 20,000 tons. As a result of high standards demanded of American manufacturers by aniline oil consumers at the beginning of the war, the quality of oil produced here has been higher than any previously marketed.

Aniline Salts.—This market has followed more or less closely the vicissitudes of the aniline oil market, and prices have dropped toward the end of the summer and since in proportion to the declines in oil. Compared with the consuming demand for salts, production has been more or less heavy, and as the year closes the prevailing price is from 28c. to 30c. for spot deliveries of hydrochloride.

Nitro Benzol (Oil of Myrbane).—Much of the domestic production of this benzol product was more or less unsatisfactory early in the year, as a considerable portion of the output of some factories had not been up to standard and many rejections were made. At present the outside market is dormant, with 16½c. to 17c. the prevailing price for the prime commercial, and up to 18c. for the refined.

Toluidine, the chief dye intermediate made directly from toluol, is being produced by perhaps half a dozen manufacturers with varying success. At the present time there are but two producers who are separating it into the para and ortho, and these only in a limited way, owing to the manufacturing difficulties encountered in the separating process. One large producer whose toluol is costing but a fraction of the ruling market price, is preparing to make the ortho and para.

Xylidine.—Due to the fact that supplies of xylol had not been particularly abundant, and the relatively small yield of the xylidine, production has not been particularly successful, and there are few manufacturers who have been able to turn out supplies in a commercial way.

Picric Acid was subject to wild speculation at the beginning of the war, but this subsided more or less during 1916. There were not the fabulous orders for foreign government nor the wild promises of manufacture that obtained earlier in the situation, and although there were some important orders placed for South American governments, as well as for the Allies, the business was well centered in comparatively few hands.

Trinitro-toluol was produced by but six large manufacturing concerns, and while the orders were not as heavy as in the preceding year, some large business has been placed, usually at somewhat lower levels. On recent United States ordnance department bids, the lowest proposed for the crude T.N.T. was 43c., and for the refined 63.5c.; both prices f.o.b. works.

Of the nitro compounds used in the manufacture of dyes, *paranitraniline* came in for most attention. Several manufacturers have within recent months started operations, but the majority of these are far behind in deliveries. This fact together with the heavy demand

both for domestic account and for export has kept the price at high levels. Supplies even now are scarce, and spot goods command from \$1.60 to \$1.70 per pound, with contract quoted at from \$1.15 to \$1.30, depending on seller and length of contract. Little interest, however, is now shown in future positions by consumers.

Dinitrotoluol is being made on a comparatively large scale, but manufacturers are chiefly using the product for their own consumption. Large explosive manufacturers are quoting at from 55c. to 60c. for important business.

Of the primary amines and derivatives, *alpha naphthylamine* commanded special attention. Large dye manufacturers have been using their output in their own processes, and independent manufacturers have at all times found a ready market for their supplies. Spot price ranged with moderate steadiness at \$1.25 per pound for immediate delivery, and from \$1 and up on contract.

Dimethyl aniline of the secondary amines and derivatives has been quiet, and prices have gradually been subject to declines, the prevailing levels being 55c. to 60c.

Diphenylamine.—The chief use for this has been as an explosive stabilizer, although some demand for use in dyes was noted. The production has been extremely limited, and important producers have sold up on contract.

Among the diamine group, *paraphenylamine diamine* has been subject to most demand, and the limited production keeps the price at the relatively high levels of from \$3.25 to \$3.75 for immediate deliveries.

Metaphenylene diamine production has been nominal, and the limited output has been rapidly absorbed by dye makers.

Metatolylene diamine is being produced in a few isolated cases by outside manufacturers, but by far the larger proportion of output has been by dye makers who consume their own product.

Betanaphthol has been produced on a large scale, and the number of manufacturers has been increased to about twenty. Heavy demand at the beginning of the year kept the price high at from \$1.75 to \$2 for the technical, and up to \$2.50 and \$2.75 for the sublimed, depending on seller and conditions of sale. The increased production, however, together with a lessening of demand, caused prices to drop to their present level of from 80c. to \$1.

The amido phenols and derivatives attracted considerable attention, particularly *H acid* (*amido naphthol disulphonic acid*), which is in keen demand, with restricted production owing to difficulties in manufacture. The two largest producers have and are using the product for their own consumption. Important foreign and domestic orders are unfilled, as supplies are not obtainable. Preparations are being made to turn out this product on a fairly large scale, and promises are made that the situation will be less tense in the future.

Salicylates have weakened gradually owing to over supplies and the prices have dropped from levels in the neighborhood of \$4 to the present prices of from \$1 to \$1.15, for both the *sodium* and *salicylic acid*. *Salol* has declined from the high level of \$9 in second hands to the prevailing price of \$2.25 to \$2.30.

DYESTUFFS

Activity during the year was confined to transactions in surplus German stocks and to an increased production of domestic colors.

Foreign Dyes.—Swiss and French colors were imported, but rarely reached the open market as ship-

ments to this country were invariably sold prior to arrival. While there has been no absolute scarcity as far as bulk is concerned of German colors during the year, prices have again ruled high, many hundred per cent above those prevailing before the war. With the possible exception of the alizarin colors, there was little difficulty noted in obtaining the various type productions at a price. Of the foreign colors, reds and blues, were at all times in brisk demand, but a good call was noted for a full line. Rhodamine B and 6G, eosine, fuchsine, Bismarck brown R and Y and primuline were colors mostly in demand during the latter part of the year. Prices toward the close of the year were lower than at any time since the beginning of the war. The two visits of the under-sea merchant vessel "Deutschland," carrying dyes and chemicals, came in for much public attention. The cargo on the first trip was much exaggerated. In tonnage it did not exceed three days' requirements of the entire American consuming industry. The colors, however, were concentrated, so that possibly the cargo represented four or five days' supplies for our textile and other color-consuming mills. No definite information has so far come to hand in regard to the bulk or the concentration of the "Deutschland's" second cargo. Unless a number of under-sea vessels are to engage regularly in this traffic, American color manufacturers do not look for very serious competition from this direction while the war lasts.

Domestic Dyes.—Blacks, of course, came in for most attention. A large number of concerns began the manufacture of sulphur black. Many difficulties were encountered, owing to inexperience and the difficulties of securing raw materials. Some very inferior color reached the market. Rejections, however, were seemingly the best development the trade had. It soon became evident that a good fast color must be produced or operations must cease, and good fast colors were turned out. A high percentage of the sulphur black produced to-day ranks well up with that of Continental Europe. Toward the end of the year one of the large explosive manufacturers not heretofore manufacturing colors began the delivery of this color. Other colors will shortly be marketed. Direct black, from a market viewpoint, probably attracted more attention than any other color during the year. Domestic manufacturers could not turn out sufficient material to answer the requirements of the trade and sales of a well-known brand were made above the \$2 level. Two and one-half years after the outbreak of the European war finds the American dye maker turning out practically a full line of aniline colors, with a few manufacturers producing from an anthracene base and vast experimental work progressing on all lines. The government census of dyestuffs came as an invaluable aid to the manufacturer here, who had been working entirely in the dark. There was no method of ascertaining the consumption of any one intermediate or color. The census allowed of a vast amount of analytical work. For example, orange II (sodium salt of p-sulphobenzol-azo-beta-naphthol), a popular color, not difficult to manufacture, is now selling for approximately \$3, prompt delivery. For contracts domestic manufacturers quote \$1. The imports of this color for the 1913-1914 fiscal year were 127,550 lb., valued at \$10,116. This is an average of \$0.079 per pound. It should be borne in mind, however, this price is net in bulk at German shipping point, does not include duty, containers, transportation or other incidental charges. Under the new tariff, effective at the close of the war, this color as well as all others will be protected by only a 35 per cent duty. Exports of domestic dyes and dyestuffs reached an amazing proportion. For the nine months ending September a

total outward business of some \$5,265,000 had been transacted. These colors went to practically every neutral country and the states of the Entente. Doubts are expressed as to whether American exporters can maintain this trade after the end of the war.

Heavy Chemicals

The output of practically every product in this classification during 1916 was the heaviest in the history of the industry.

Potassium Salts.—As compared with 1915, the past year was a comparatively tame one, in regard to the sale of surplus stocks of German potash. Supplies had dwindled to such small proportions that large transactions were no longer possible. For such small quantities of "muriate" as have been available up to \$500 had been paid, with a recession in price toward the end of the year. Some attention is now being given to the Japanese product, which is to be had at considerably lower prices. Sales, however, have been principally confined to chemical manufacturers of potassium salts. The search for potash within the United States has so far resulted in a production from kelp, cement, alunite, feldspar, and from natural deposits, of 45 tons daily of K_2O . One-half, or possibly more, is produced from the natural deposits of the Nebraska lakes. A production of 45 tons per day is about 6 per cent of the average daily consumption of K_2O in normal times.

Ammonium Salts.—Although no definite figures are yet available, the production of *ammonium sulphate* was unquestionably the largest in the history of the American industry, as a larger number of by-product coke plants were operated than ever before, and supplies of British sulphate were cut off, owing to the governmental embargo. Of the other ammonium salts, *nitrate* came in for a vast amount of prominence, for the manufacture of high explosives. The seven or eight American producers for the first six months of the year had considerable difficulty in fulfilling contract requirements. In the early fall there was a lull in the situation, with declining prices, but subsequently a sharp recovery was noted. At the present time exports, particularly to France and Italy, are exceedingly heavy, and large factors are quoting higher prices for contract than the prevailing spot figures.

Nitrate of Soda.—For the first time in the history of the industry the imports of nitrate of soda from Chili exceeded the million-ton mark. Prices ruled on high levels, opening the year at \$3.25 per cwt., and closing at near \$3.40. Sulphate of ammonia and nitrate of soda usually compete on a basis of unit of ammonium content, but owing to abnormal conditions prevailing, supplies of the sulphate were limited, and this situation did not exist during 1916 to any considerable extent.

Mineral Acids.—As the imports of sulphur ore (pyrites) for the nine months ending September, 1916, were in excess of the million-ton mark, it is quite safe to assume that the production of *pyrites Sulphuric acid* was again greater than the high-water mark of the previous year. The domestic and Canadian production of pyrites was also reported to have been larger than for any corresponding period. Brimstone acid has been subject to a heavier demand than ever before for use in explosives, and also in the manufacture of dyes. Early in the year prices ruled at high levels, but as production increased there was a let-up in the keen demand, and slowly but surely the price levels receded. For the last few months, however, there has been increasing call for the acid, and at the present time there is an actual scarcity; many important manufacturers are not taking business for prompt

delivery at this time, having well sold up on contract. There has been much complaint regarding the poor quality of the pyrites acid produced in the South. Acid prices have varied considerably, depending largely on location of plant. Northern producers are quoting from \$26 to \$28 per ton for the 66-deg. brimstone, and from \$16 to \$18 per ton for the 60-deg. brimstone. Pyrites acid is held at high levels, and Southern manufacturers are asking up to \$18 and \$20 per ton for the 66-deg. grade, f.o.b. plant. The price for the 60-deg. pyrites ranges from \$12 to \$15 per ton at works.

Muriatic Acid.—Demand for this acid has been spasmodic, although there has not been the recent advances that obtained in the sulphuric market. Some big orders have been placed lately, however, especially for contract. The 20-deg. goods are quoted at from 1½c. to 1½c., and up to 1½c. and 1¾c. for the 22 deg.

Nitric Acid.—Early in the year there was heavy demand in evidence, but since the late summer prices have gradually eased off, owing to the fact that production had increased, without the corresponding expansion of demand. The condition has improved during the last month, however, in sympathy with the changed sulphuric situation, and at present the 42-deg. grade is quoted at about 6c., and the lower concentrations at proportionately lower prices. Owing to the dangerous quality of the higher strengths, but few manufacturers are willing to concentrate above the 42-deg. mark, and prices on these grades rule high.

Organic Acids.—Acetic acid, glacial, started off in January, 1916, at about 30c. to 32c., and after some fluctuation, followed by gradual declines last spring, the low mark of 15c. was reached in October, when a complete metamorphosis occurred in the situation, and almost over night in the middle of November the price jumped to 30c., and has advanced to the present price of from 33c. to 35c. Heavy export demand, coupled with the starting of a strike at the plant of one of the largest producers, created the change. The 80 per cent grade is in heavy demand and has increased from the price of 7½c. to 8c. prevailing in November to the present figures of 14c. for the commercial, 16c. for the redistilled, and up to 17c. for the pure. The lower strengths advanced in sympathy, although little demand is in evidence.

Lactic Acid.—The market continues rather steady, at 5c. to 5¼c. for the pale 22-deg. rectified.

Phosphoric Acid.—Supplies are nominal, and have been for some time; the few domestic producers are well sold up into the future, and but limited supplies of the 47 to 50 per cent liquid are to be had at 13c. to 14c.

Oxalic Acid.—Steady imports from Norway and Holland, added to the increased domestic production, have caused an oversupply on the market, and following gradual declines the prevailing prices to-day range from 43c. to 48c., depending on grade.

Cyanides.—The fact that the electrical power of the only large producer of cyanides in America was curtailed recently has caused a wildly speculative market, with attendant soaring prices. From the price of 25c. to 30c. for sodium prevailing at the outset of the year, gradual advances obtained, until within the last three weeks prices jumped from 80c. to the abnormal figures of \$1.75 and \$1.80. The potassium is even higher in price, and sales were recorded just prior to the holidays at \$2.05 per pound. The demand is still heavy for mining operations, and supplies are nominal.

Chromium Salts.—These chemicals have had most particularly interesting careers during 1916. At the beginning of the year potassium bichromate was held at 45c., and increased gradually until in the spring the high levels of 90c. to 92c. for potassium and 65c. to

68c. for sodium were reached. During this time there was keen speculation in evidence, and manufacturers were having difficulty in filling orders. However, realizing the abnormal condition of the market and susceptibility to influences, manipulation began, in order to purchase resale supplies that they might be turned at a profit on orders. The market weakened under this pressure and gradually was reduced to the levels that now prevail, viz., from 40c. to 42c. for potash. Supplies which never were abundant are at this time scarce, and held with some firmness.

The present market in bichromate of soda is uncertain. The lowest figures that have obtained at any time during the year prevail. From 19c. to 20c. are the prices to-day. At the start of the year the price was 25c., which increased under heavy speculative demand to abnormal levels in the spring, receding gradually throughout the year to the present levels. One of the largest consumers in the country is now making its own chromium salt. Consumers generally had well contracted for their supplies. A Canadian owned production now competes with domestic manufacture. The general output has increased to a marked degree. The skillful manipulation has brought prices to their present levels. So great was the speculation during the high levels that many small buyers were caught, and heavy losses were incurred.

Copper Sulphate.—There has been a moderately strong demand all during the year, with high prices ruling, particularly during March and April. The output of the three largest producers is well sold up, and supplies in second hands are now more or less moderately small. Anticipated orders from abroad, however, especially from Greece, for use in spraying vineyards, not having materialized, the market is somewhat easier at present, and the large 98 to 99 per cent crystals are available at from 12c. to 12½c.

Alkalis.—Caustic soda, of course, has been traded in to an enormous extent, and the consuming demand has been on a large scale all during the year; this has been a highly speculative article, and gambling interests have played an important part in the price movements. Prices ranged from 5½c. to 5¾c. in January, 1916, to 6¾c. and 6¾c. in March, to the levels of 4.35 to 4.45 that now obtain. The fact that three new manufacturers have entered or are about to enter the field is also an important factor in bringing about the present prices. Contract business is almost at a standstill compared to usual activity. Producers are standing "pat" in an endeavor to keep the prices up.

Soda Ash.—Following the recent peace rumors, the market has receded somewhat, although as much of the large manufacturers' supplies are under contract; there is no pressing of stocks for sale. The spot price ranges from \$3.05 to \$3.10 for the 58 per cent light, flat basis, and on contract over 1917 at from \$2.65 to \$2.70. Some sales were made several weeks ago for 1918, but consumers are not booking business now so far into the future. At least two large important new producers entered the field.

Bleaching Powders.—The market for the last several months has shown steady declines from the high prices that were in evidence at the beginning of the year, which opened at 14c. to 15c. The difficulty of securing adequate supplies of drums suitable for export has increased perceptibly as time advanced. The spot price for bleach in large domestic drums is now 4½c., and for good export drums from 6¾c. to 6¾c., showing a difference of a full 2c. per pound for the different packing. Export demand is rather spotty, but generally heavy, Scandinavia and England, particularly, buy-

ing in large quantities for their paper and pulp mills. The present manufacture of bleach in this country has been fairly well contracted for by consumers and dealers, and supplies offered on the open market are therefore limited. The production of bleaching material by consumers for their own use increased as never heretofore.

CURRENT MARKET REPORTS

The Iron and Steel Market

The second half of December witnessed a sudden and marked slowing down in the iron and steel markets. Production continued at the fullest rate, except as curtailed by insufficient transportation facilities, many furnaces being banked through coke being slow en route, or through coke operators not having cars into which they could draw their ovens. Apparently the slowing down started with the German peace overture, which became public news on December 12, but there had previously been predictions that steel bookings would be much lighter in December than they had been in November, when the Steel Corporation's unfilled tonnage increased by a million tons only for the third time in the corporation's history. The advent of the holidays always slows down market activity, and thus there has been a combination of circumstances.

The iron and steel producers are little concerned with the market, their chief concern being the filling of the orders already on books, as there is prospect of a railroad blockade throughout the winter as severe, possibly more severe, than that of 1902-3, which railroad men pointed out at the time was the first in the history of American railroading, and might prove to be the last.

The common complaint is "car shortage," that being what the shipper experiences. It cannot be admitted, however, that there are fewer cars in the country than would be needed to carry the freight if they were loaded approximately to capacity and if they were kept in service. There has been no general increase in the minimum load for iron and steel products in about 17 years, practically the life of the steel-car industry. During that period the railroads have spent enormous sums replacing cars of small capacity with cars of greater capacity, but in many instances use is not made of the increased capacity. Consignees have been using cars for storage purposes, unloading their goods when they were ready, as \$1 a day for warehouse facilities, paid for when needed, and costing nothing when not used, proved a small expense. The demurrage rates were greatly increased Dec. 15, and this may help. The railroads are certainly short of motive power, and the inadequacy of motive power was particularly great when cold weather arrived, as locomotives that were able to get along in mild weather played out completely in cold weather.

Early in December a proposition was made that the iron and steel industry should shut up shop for a week or ten days to allow the railroads to clear their lines. The industry had no machinery even for adopting such a program, much less for carrying it out, while the desire probably was lacking owing to natural doubt as to the efficacy of a remedy never before tried. As car shortages have proved most serious in the Connellsville coke region, an automatic slowing down is probably in process. Beginning the week before Christmas, a number of furnaces were banked, and the number has increased steadily since then. Some of the steel works, however, have moderate stocks of pig iron, but the use of cold iron itself slows down production a trifle.

PIG IRON

A few advances in pig iron, practically negligible, have occurred since last report. The market is substantially at a standstill, with producers almost fully sold for the first half of 1917, and with very considerable tonnages on their books for the second half. As prices are easily the highest since 1880, and the excitement is over, a quiet market is to be expected for some time, except for the buying of some descriptions of pig iron in small lots for prompt shipment at a premium.

UNFINISHED STEEL

Unfinished steel has advanced about \$5 a ton since last report. Market prices are made by occasional sales, sometimes merely by bids. The buying demand has been narrow, but the offerings have been still scantier. Ordinary soft-steel billets and sheet bars are now quoted at \$60 to \$65, Pittsburgh or Valley, the lower price being readily bid for export, while it appears that the higher price has been paid occasionally for prompt lots. Wire rods command \$75 to \$80, the higher price having been paid on a round lot for export to Canada. Why wire rods should bring so much more than the billets from which they are made and the wire products they are customarily made into is not readily explained. At \$75 per gross ton, wire rods are 3.35c. per pound, or more than the base price of either plain wire or nails. Forging billets are quoted at \$80 to \$85.

FINISHED STEEL

The sheet market has continued to stiffen, and while prices for late deliveries may not be quotably higher, it is certain that higher prices are obtained for early deliveries than a fortnight ago. Otherwise, the finished-steel market is substantially unchanged as to prices, except for the advance of \$2 a ton in bars, shapes and plates, to 3c., 3.10c., and 3.60c. respectively, which occurred about Dec. 20. This advance, however, can hardly be viewed in the same light as the various advances that preceded it. They occurred, except perhaps as to certain advances early last August, when the buying pressure was extremely heavy, while this advance occurred when the market had been distinctly quiet for a week. Students of steel market history will perhaps feel the atmosphere of old times, for at the end of a general price-advancing movement there has usually been a last advance which served to "clinch" or make sound the business placed on books at the next lower prices.

IRON ORE

December shipments of Lake Superior iron ore down the lakes were unprecedentedly heavy, amounting to 1,085,900 tons, and bringing the season total by lake to 64,734,193 tons. As more than 1,500,000 tons was doubtless moved by all-rail routes, the total shipments of the Lake Superior region, on the American side, must have exceeded 66,000,000 tons, against 47,000,000 tons in 1915, and 50,000,000 tons in 1913, the record year. There is no possibility, therefore, of there being a scarcity of iron ore in the winter or spring, fears as to which were expressed last spring. It is coke and limestone that are giving the blast furnaces their anxious time.

Non-Ferrous Metal Market

Dec. 26.—The chief factor influencing the market during the past two weeks has been the peace talk, and while some of the metals, especially lead and tin, have remained firm, buying has been curtailed to a great extent. The holiday season also had its effect, as buying is normally dull during the last two weeks of the year. The drop in the stock market did not have such a

great effect on the copper market as was anticipated, owing to the sold-up condition, but it did have the effect of inducing some consumers to sell surplus stocks which they had on hand.

Copper.—Since Dec. 11, on which day copper reached its highest point of 36c. for prompt electrolytic, the price has dropped, and electrolytic and Lake are now quoted at 31c. to 32c. for prompt delivery. New copper restrictions were put in effect in England, allowing no one to buy outside the United Kingdom without a permit, and the use of copper is forbidden except for government work. Business has been dull, with the exception of some reselling by consumers. Buyers are holding off until next year, and producers are believed to be pretty well sold up for the biggest part of next year, making it difficult to see how prices can go very low for some time to come. Exports up to Dec. 22 were 17,763 long tons.

Tin.—Straits tin has declined from 43.50c. on Dec. 11 to 40.50c. on Dec. 22. The London market has also declined considerably during the last two weeks, and £185 is quoted for prompt Standard and Straits. Insurance rates on shipments are higher, and arrivals continue to be light. As in the case of the other metals, the peace talk and the holidays have curbed buying. Several hundred tons of Banca tin arrived Dec. 21, and was offered at 40.50c., which is the present spot quotation for Straits.

Lead.—The lead market has remained strong in spite of the peace talk, and no January or February lead at the trust price of 7.50c. is to be had. Independents have cut their prices slightly from 7.75c. to 8c., down to 7.50c. to 7.62½c.

Spelter.—The peace talk stopped trading in the spelter market, and prompt spelter has declined from 12.30c. on Dec. 11 to 10.95c. on Dec. 22. Buyers are holding off, awaiting developments. Zinc-ore prices are lower, and producers showed more disposition to sell on Dec. 22, resulting in a small amount of business at lower prices.

Other Metals.—Antimony remains unchanged in price at 14.37½c. for Japanese and Chinese. The market has been dull. Aluminum is quoted at 60c. to 64c. for No. 1 virgin metal. Magnesium remains at \$3.50 per pound, electrolytic nickel at 50c., and cadmium at \$1.50. Platinum is quoted at \$99 per ounce, tungsten ore at \$17.50 to \$20.00 per unit, and silver at 75½c.

General Chemicals

WHOLESALE PRICES IN NEW YORK MARKET DECEMBER 7.

Acetone, drums,	lb.	22½	23
Acid, acetic, 25 per cent,	100 lb.	3.50	3.65
Acetic, 50 per cent,	100 lb.	7.00	7.15

INDUSTRIAL

Financial, Construction and Manufacturers News

Financial

Alaska Hydraulic Mines, Inc. Catipal, \$1,000,000. Incorporated in Delaware to mine gold, silver, copper, lead, zinc, etc., by Norman P. Coffin, Herbert E. Latter and Clement M. Egner, all of Wilmington.

The Alabama Wood Oil Company, Mobile, Ala., has been incorporated with a capital of \$15,000 to manufacture wood, animal and mineral oils. The incorporators are O. E. Childs, Moline, Ill.; J. E. Drysdale, W. W. Bailey, Davenport, Iowa, and the American Wood Oil Co., Wilmington, Del.

Amber Chemical Corporation, New York, has been incorporated with a capital of \$30,000 to manufacture chemicals and drugs. Incorporators are A. Sinclair, 15 Wall Street, New York; A. L. Bykeeper, 1642 Decatur Street, Brooklyn; C. G. Francis, 15 Wall Street, New York.

Anthony-Hammond Chemical Works, Inc., New York, has been incorporated with a capital of \$100,000 to manufacture benzoate, beta naphthol products, etc. The incorporators are E. N. Carey, M. Tischer, H. C. Quinby, 165 Broadway, New York.

The Antimony & Compounds Company of America has been incorporated in New Jersey with \$200,000 capital. The company formerly operated in Belgium. The office of the company will be in the town of Pisataway, Middlesex County, and the incorporators are: Joseph Dhavernas and Eric Goodwin, both of New Brunswick, and Robert Louis Hosnet of New York. Chemicals will be manufactured.

Barnett-Burgess Chemical Company, Hackensack, N. J. Capital, \$100,000. Incorporated to buy, sell, extract and deal in alum, sodium, silicon and metals, by C. O. A. Corth, Hackensack, N. J.; Robert A. Van Voorhies, Jersey City, and Arthur R. Oakley, Pearl River.

Bowditch Dye Works, of Putnam, Conn., incorporated with \$50,000 capital by Detoxer Elliott, George A. Vaughn of Thompson, Benjamin Linesey, Jr., of Waukegan, and Fred Ashton of Putnam.

Bradford Oil & Gas Co., Bradford, Pa., has been incorporated with a capital of \$125,000 to produce, refine and prepare for market petroleum, coal, natural gas, etc. Incorporators: A. S. Williams, F. H. Wright, Bradford, Pa.; A. E. Magee, Dover, Del.

The Bridgeport Iron & Metal Co., Bridgeport, Conn., has been incorporated with a capital of \$10,000. Incorporators are William and Aaron Olderman of Ansonia, and C. Nowits of Bridgeport.

The Brompton Pulp & Paper Company, Ltd., incorporated in Canada with \$9,000,000 capital. Headquarters, Montreal.

The Bryant Paper Company of Kalamazoo, Mich., and the Oxford Paper Company of Rumford Falls, Me., have purchased the Edward Hartington Pulp & Paper Company of St. Johns, N. B., for \$3,000,000. A new company was organized to be known as the Rumford Pulp & Paper Company and will have offices in New York. Improvements on the mill property, costing \$250,000, will be made immediately, insuring a capacity of 100,000 tons daily. The incorporators are P. J. Chisholm, president; L. M. Bickford, vice-president; F. E. Tufts, treasurer; L. H. Drummond, secretary, all of Rumford Falls; P. Milham and W. P. Milham of Kalamazoo are heavy stockholders and directors.

The Rutherford-Judson Corporation has had a remarkable year, as evidenced by a letter issued by Chauncey Brock & Co., New York and Philadelphia, bankers. The company has plants in Newark, Roston and Baltimore, and it is estimated that for the first year in months this year the corporation earned \$3,600,000. September earnings were almost \$550,000 while in October the figures exceeded \$670,000. The ratio of increase has been a full head. The beginning of the construction of new plants begin in the late summer. The letter has the following to say in regard to the Rutherford-Judson products: "This year our corporation is producing large quantities of high-grade acids on war orders. To its ordinary chemical production, including the manufacture of milline acid, it has added muriatic acid, carbonic acid crystals, sulphuric acids and picric acid. The company's output of picric, carbonic, sulphuric, nitric and mixed acids is used mainly in the manufacture of explosives. The demand for the company's output of

acids for explosives has greatly curtailed the time which it has been able to devote to the development and production of dyes. But the company's plants, both its main factories in New Jersey and the new factories which have been constructed in Boston and Baltimore, have been carefully equipped so that on short notice they might be readily converted to the manufacture of dyes, when the abnormal demand for acids stops.

The Central American Oil Co., Dover, Del., capital \$5,000,000, is incorporated to acquire and develop oil lands by Geo. W. Dillman, F. D. Buck and K. E. Longfield, of Wilmington.

Chambers-Haber Chemical Co., Cleveland, Ohio, capital, \$50,000. Incorporators: Charles M. Swingle, Henry W. Haber.

Citizens Oil & Gas Company, Wilmington, Del., capital, \$150,000. Incorporated to manufacture and market crude oil, petroleum, etc., by Herbert E. Latter, Norman P. Coffin and Clement M. Egner.

Colossus Copper Co., Dover, Del., has been incorporated with a capital of \$3,000,000 to mine for gold, silver, lead, zinc, etc. The incorporators are F. R. Hansell, George H. B. Martin, S. C. Seymour, of Philadelphia, Pa.

Colorado Pure Lead Corporation, New York, has been incorporated with a capital of \$115,000 to manufacture drugs, acids, alkalis, esters, extractions, etc. Incorporators are H. Alexander, L. M. Woodworth, J. L. Rawlinson, 40 Wall Street.

Conservation Oil & Gas Co., Parkersburg, W. Va., capital, \$150,000. Incorporated with a capital of \$25,000. Incorporators are C. S. Shepherd, Laura E. Shepherd, Emily D. Bukey, Estelle M. D. O'Blenness.

Coyote Mining Company, Northport, Wash., capital, \$250,000. Incorporators: J. E. Herron, L. W. Cook and George Osterhout.

Cuban Oil & Gas Co., Tulsa, Okla., has been incorporated with a capital of \$25,000. Incorporators are R. M. Kincaid, W. C. Wolfe, R. J. Conaway.

The Cuban Sugar Mill Corporation is being organized in Duluth, Minn., with a capital stock of \$5,100,000.

The Doerr Glass Company, Vineland, N. J., has been incorporated to manufacture and deal in glass. Capital, \$50,000. Incorporators: Herman R. Doerr, Francis Doerr and Albert J. Doerr.

Eklawa Oil & Gas Company, Bristow, Okla., capital, \$100,000. Capital stock, \$50,000. The incorporators are Henry Lowenstein, Conrad F. Ekfelt, St. Louis, Mo., and Sam K. Wasaff, Bristow.

The Elmstrom Leather Company, Boston, Mass., has been incorporated with \$25,000 by Robert Elmstrom, Elmer L. Elmstrom and Hilda E. Johnson.

The Eureka Crucible Flake Graphite Company, Inc., of Saratoga Springs, has been chartered in New York State to carry on a general mining business. Directors: Emmit T. Lee, Frank W. Lee and Will H. Smith.

The Famol Company, Washington, D. C., has been incorporated with a capital of \$35,000 to manufacture chemical preparations of various kinds. The incorporators are W. G. Mertz, F. L. Pickham, F. Vansant, all of Washington.

Feldman-Blair Petroleum Company, Dallas, Texas, has been incorporated to have their name changed to the National Oil & Refining Company.

Fritz Oil & Gas Co., Zanesville, Ohio, is incorporated with a capital of \$20,000. The incorporators are O. Burkhardt, W. L. Swingle, J. L. Swingle, H. E. Baker and Frederick S. Baron.

General Synthetic Co., 234 Lincoln Avenue, Cleveland, Ohio, incorporated with \$100,000 capital to manufacture chemicals.

Globe Refining Company, Houston, Tex., capital \$10,000, is incorporated by R. L. Blaffer, W. S. Parish and S. B. Parish.

Graphite Milling Company, Birmingham, Ala., capital \$100,000, with \$75,000 paid in. Incorporators: Roswell H. Cobb, Ray M. Stearns, and C. D. Brown. The company is understood to have in mind the operation of graphite mills.

Guernsey County Oil Producing Company, Cleveland, Ohio, incorporated with \$100,000 by M. A. Davidson, J. E. Mathews, G. H. Knippenberg, Maurice Masche and H. O. Evans.

The Gunderson Mining Company, with its principal place of business at Deerwood, has been incorporated by C. C. Adams,

president and treasurer, Cuyler Adams and R. M. Adams, secretary, all of Deerwood, D. R. Cotton and A. H. Warren, Jr., vice president, both of St. Paul. The capital stock is \$50,000.

The J. Frank Hays Company, Camden, N. J., has been incorporated with a capital of \$25,000 to manufacture leather. The incorporators are F. R. Hansell, J. A. McPeak, I. C. Clow.

The Hay Creek Oil Company, Santa Anna, Tex., capital \$20,000, is incorporated by Jason Tyson, John Campbell, S. J. Fieralt, and others.

The Holland Furnace Company, Holland, Mich., will increase its capital stock from \$250,000 to \$300,000 to finance a new plant.

Hoyt-Davis Oil Company, Houston, Tex., is incorporated with \$200,000 by G. H. Davis, L. C. Abell, W. W. Parker and J. M. Brown, all of Houston.

The Imperial Chemical Co., Grand Rapids, Mich., has been incorporated with a capital of \$100,000 to manufacture all kinds of spraying material and disinfectants. The incorporators are W. L. Moor, C. R. Slight, J. D. Cass, D. C. Scribner, F. J. Pickett, of Grand Rapids.

Intermediate Chemical Corporation, New York, has been incorporated with a capital of \$1,000. Incorporators are M. Reed, A. C. Burrage, Jr., H. Lawson, 497 Dean Street, Brooklyn.

Lester's Tanning Company, Boston, Mass., is incorporated with a capital of \$300,000, 12,000 shares at \$25 each. The directors are E. C. Fischer, president; Alexander E. Rose, Roxbury, treasurer, and Alfred Karp.

Industrial corporations and domestic railroads have borrowed \$2,073,719,500 since Jan. 1, according to figures compiled by the *Journal of Commerce*.

New corporations to manufacture war material, dyes and chemicals, to produce oil and refined oil products, and to build ships, have a combined capitalization of \$922,435,000.

The Krebs Pigment & Chemical Company, Newport, Del., has increased its capital from \$1,000,000 to \$2,000,000. The Krebs Oil & Gas Co., Tulsa, Okla., has been incorporated with a capital of \$10,000. Incorporators are Dr. J. J. McKanna, Dr. D. W. Conger, W. H. Brown.

The Lackawanna Iron & Steel Company, interests at Lebanon, Pa., in the Cornwall ore mines and also the Freeman interests in the Cornwall Railroad, ore mines and furnaces at Cornwall have been purchased by Charles M. Schwab. This gives Mr. Schwab control of the Cornwall ore mines. He will own outright the American Iron & Steel plants, including the \$2,000,000 steel mill plant and the twin Polebrook furnaces, and will direct, under lease, the Twin Bird Coleman furnaces at Cornwall, Pa., the Cornwall Railroad and the Freeman interests in the Cornwall mines.

Leedsdale Foundry & Manufacturing Company, Wilmington, Del., has been incorporated with a capital of \$30,000 to manufacture iron, steel, etc. The incorporators are H. E. Latter, N. P. Coffin, C. M. Egner.

The Liberal Oil & Gas Company, Dallas, Texas, has been incorporated with a capital of \$125,000. Incorporators are A. M. White, G. W. Sawyer, J. C. Mahoney.

Los Angeles Glass Co., Los Angeles, Cal., Capital \$10,000. Incorporators, John Spring, Kate L. Spring and George W. Averill.

Met-Oh-Lene Co., Inc., New York, has been incorporated with a capital of \$32,500, to manufacture dyes, chemicals, paints, etc. The incorporators are L. Frank Meyer, H. E. Reid, 165 Audubon Ave.

Middle West Fertilizer Co., Springfield, Mo., is incorporated with a capital of \$100,000. The incorporators are J. H. Campbell, Douglas, Augustus H. Dean, Otto A. Koch, C. H. Leach and James B. Yaw.

Mountain Sulphur and Oil Company, Houston, Texas, capital \$100,000, is incorporated by E. A. Cox, D. E. Teague, M. C. Hale.

The oil plant of the National Oil Company, formerly leased to the Shell Oil Company at Rodeo, has been purchased by Frank Milliss for \$50,000.

Nevin Chemical Company, Wilmington, Del., is incorporated with a capital of \$200,000 to manufacture chemicals, drugs, etc. The incorporators are Herbert E. Latter, Norman P. Coffin and Clement M. Egner of Wilmington.

New Healdton Oil Company, Ardmore, Texas, is incorporated with a capital stock of \$150,000. The incorporators are Jake L. Hamon, Chicago, Harold Wallace and J. S. Miller, Ardmore.

Oneta Refining Company, Oneta, Okla., is incorporated with a capital of \$50,000. The incorporators are F. B. Misener, Charles F. Blitt and C. D. Brown.

Optimis Manufacturing Company, Portland, Me., has been organized with \$150,000

capital to manufacture and deal in varnishes, paints, etc., J. Stewart Holliday, Dorchester, Mass., is president. M. A. Reunard, Dorchester, is treasurer.

Oxytherm Chemical Company, San Francisco, Calif., has been incorporated with a capital of \$250,000. Incorporators are H. Carr, John Robert L. McNealey. The company will deal in alkalis and chemicals.

The Pacific Coast Steel Company stock owned by the T. P. Donahue interests, H. Carr, John Robert L. McNealey. The company will deal in alkalis and chemicals.

The Pacific Coast Steel Company stock owned by the T. P. Donahue interests, H. Carr, John Robert L. McNealey. The company will deal in alkalis and chemicals.

The Paragon Refining Company, Toledo, Ohio, has been incorporated with \$750,000 capital stock over the plant and other property of The Paragon Refining Co. of Ironville, Va. The incorporators are J. C. Carr, W. C. Carr and Nathan Fuller. The company will be reorganized. The plant is located on the Maumee River and covers 21 acres. It has a capacity of 45,000 bbls. per month. The plant and additional property are contemplated to bring the capacity up to 60,000 bbls.

Peerless Paint Products, Inc., Bronx, New York, is incorporated with \$40,000 capital to do business in paint, oil and varnish. Incorporators: H. M. Kahn, S. Traub, S. E. Rosenstein, 1221 Brook Ave., Bronx.

Redux Oil and Gas Company, Tulsa, Okla., \$50,000 is incorporated by Thomas D. Lyon, H. P. Rambo, L. G. Livesay, of Tulsa.

Reid Creek Mining Company, Seattle, Wash., capital \$250,000. Incorporators: Otto Leinhecker, Joseph R. Austin, and A. C. Crookall.

Roune County Oil and Gas Company, Charleston, W. Va., has been incorporated with a capital of \$350,000. Incorporators are L. R. Martin, F. J. Holup, L. T. Sanders, E. C. McHugh and R. T. Rosselz. The company will develop oil and gas properties in The Roune County district.

Charles M. Schwab has purchased for the Bethlehem Steel Company, the controlling interest in the Jackson and Reading plants of The American Iron and Steel Manufacturing Co., confirming a report recently circulated that the purchase would be made. The plant is a modern twin bolt and nut plant, car forging, car and railroad materials plant, and a new electrically operated steel mill. The purchase is said to involve \$3,000,000.

Seafmons Oil Co., capital \$1,000,000. Incorporated to buy, sell and deal in oil, gas and minerals, by Herbert E. Litter, Norman P. Coffin, and Clement M. Egner, all of Wilmington, Del.

Sefton Manufacturing Corporation, Milbrook, N. Y., has been incorporated with a capital of \$3,250,000. The manufacture of iron, steel, copper and products. Incorporators are D. Havens, 55 Ilanson Pl., S. C. T. Dodd, 1918 Avenue H, Brooklyn, A. E. Moore, 29 Arden St., New York City.

The A. G. Smith Corporation has secured a New York charter. Capital \$3,500,000. The company will manufacture steel and iron products. Directors are Louis H. Gunther, Samuel B. Howard and Arthur W. Britton.

Springtown Oil and Gas Co., Ft. Worth, Texas, has been incorporated with a capital of \$50,000. Incorporators are Grover Smith, Thomas Pressnal and S. T. Speer.

A group of bankers, headed by Cassatt & Co., and Frazier & Co., of Philadelphia, and White and Merritt, of New York, Lynch & Co., of this city has purchased a large interest in the Superior Steel Company of Carnegie, Pa. A new company will be formed which will have a \$1,500,000 stock. The company manufactures hot and cold rolled strip steel and has a capacity of 115,000 tons per annum.

T-P and C Oil and Gas Company, Oklahoma City, Okla., is incorporated with a capital of \$4,000. The incorporators are M. H. Teller, L. O. Pruiett, and G. E. Chaffee (Oklahoma).

The Tith Oil Company, a New York company is contemplating the purchase of the Constantin Refining Company of West Tulsa at a price said to be \$2,500,000. The Constantin Co. has a 5,000 barrel plant.

The Tomboy Gold and Copper Company has been incorporated in Arizona and will have its office in Chicago. The company is capitalized at \$1,000,000. The incorporators are Pearl Skelton, E. R. Little and J. F. Gerald.

Toromata Zinc Mining Company, Joplin, Mo., Capital \$50,000. Incorporators: W. R. Askwith, Frank L. Cody and W. W. Booth.

Transylvania Tanning Co., Brevard, N. C., has been incorporated with a capital of \$250,000. Incorporators are J. S. Silverstein of Brevard, N. O. Dworetzky, A. M. White of Rochester.

Union Coal Tar Products Corp., Del., has been incorporated with a capital of \$1,000,000 to manufacture chemicals, crude petro-

leum coal and tar products. Incorporators are S. A. Anderson, S. B. Howard, L. H. Gunther all of New York.

The United Steel Company, Canton, Ohio, has decreased its capital from \$150,000 to \$150,000.

The Utah Paraffin Oil & Wax Company has been incorporated in Utah with \$10,000 capital to mine and treat ores and metals, oil shale and its by-products. Whether the company will develop the paraffine oil deposits on the west shore of Great Salt Lake or make lamp black from the crude oil and gas wells in Wyoming is uncertain. Salt Lake business men are interested.

Officers of the company are Lawrence Greene, president; W. R. Wallace, vice president; James Ingbreghsen, secretary; treasurer, M. R. Murphy, S. Murphy, M. A. Kyser and O. W. Ewing, with the officers constitute the board of directors.

The Virginia-Carolina Chemical Company has become one of the stockholders of the American Cyanamid company as the result of the sale to the latter of the phosphate rock mines of the Amalgamated Phosphate Company, Florida, in which Virginia-Carolina Chemical had a large interest.

Weiss Drug Co., Inc., capital \$16,000. Incorporated by S. Strauss, A. Weiss and C. Weiss. To do business in drugs, medicines, paints and chemicals, 546 W. 147th St.

White Star Refining Co., Oklahoma City, Okla., has been incorporated with a capital of \$250,000. Incorporators are M. Campbell, L. Paddock, J. B. Enfield.

The Wisconsin Process Company, Milwaukee, capital \$100,000. Incorporated to manufacture and sell chemicals. Capital, \$10,000. Incorporators, A. A. Stettem, L. E. Fichaux and others.

Construction and Operation

Arizona

PRESCOTT.—Engineers and officers of the Anglo-Saxon Smelting & Refining Company were expected in New York from London, England, on Dec. 25, from where they were to go to Prescott with the intention of erecting a large custom smelter. The company is reported to be prepared to spend \$3,000,000. The party consists of G. G. Lemons, Robert L. Service, secretary of the company; Hugh Rose Croup, president, and two metallurgists.

Arkansas

FORT SMITH.—The Athletic Smelter & Mining Company of Joplin, Mo., is erecting a \$125,000 smelter at South Fort Smith. The Business Men's Club has paid \$4,600 for the trace site and railroad right of way for the company.

California

KENNETT.—The \$400,000 electrolytic zinc plant of the Mammoth Copper Company is nearing completion at Kennett, and is expected to be ready for service early in February. The plant is the most complete of its kind in the world.

LOS ANGELES.—Baker Iron Works plant erecting steel and corrugated iron, 160 x 10 ft. addition, equipped with two 25-ton electrically driven traveling cranes. To be plant on North Broadway and Castelar Street; cost, about \$65,000.

SANTA ROSA.—The North of Bay County Press Association has been considering the erection of a co-operative paper mill. Homer W. Wood of Petaluma is president of the association.

VERNON.—The California Chemical Company has prepared plans for a plant 168 x 153 ft., here.

Colorado

GEORGETOWN.—The Colorado Central Mining Company, Edward S. Wiard, general manager, is in the market for supplies for mine, mill, lumbering, and railroad construction. They are desirous of receiving catalogs from concerns who can furnish these materials.

STERLING.—An organization known as the Highland Promotion Company, made up largely of land holders in the territory east of Sterling, is planning to interview the Great Western Sugar Company of Denver, in regard to the erection of a beet sugar plant at Hill. H. B. Davis is president of the Promotion Company.

Connecticut

BRIDGEPORT.—The American Tite & Strapping Company has plans for the erec-

tion of an additional billet mill and a large rolling mill on its property near here, between Yellow Pond, Stratford and Seaview Avenues. The additions will double the present capacity.

Delaware

WILMINGTON.—The Wilmington Leather Company will erect a six-story factory at Second Street and Greenhill Avenue, to cost about \$60,000.

WILMINGTON.—The Wilmington Steel Company, a branch of the Midvale Steel Company, will build several new furnaces as soon as homes can be furnished for 1500 additional workmen.

District of Columbia

WASHINGTON.—According to the annual report of Secretary of the Navy Daniels, the Government plant at Indian Head is producing powder at the rate of 6,000,000 lb. a year, or double the output of three years ago. The sulphuric and nitric acid plants have been expanded sufficiently to take care of the entire needs of the powder factory, thus effecting a considerable saving in this direction. The cost of the powder has been reduced from \$0 to 34c. per lb.

Illinois

QUINCY.—The Monroe Color & Chemical Company has announced that it will erect a new plant here and will manufacture direct black. The company is an outgrowth of the Monroe Drug Company of Quincy, which manufactures various dyes and pigments. The company has been seriously handicapped by the war. Much of the product of the new plant will be used in the Monroe Drug Company's plant. The factory comprises six buildings and the following intermediates will be made: Benzidine, metaphenylenediamine, aniline and H-acid. The plant is complete in every respect and the product has been carefully worked out. E. N. Monroe is head of both the Monroe Drug Company and the Monroe Color & Chemical Company, and his son, Neal Monroe and Earl Cunnins, have perfected the processes and are in charge of the plant, the latter in the capacity of chief chemist.

Indiana

EVANSVILLE.—The Graham Glass Company has announced that it will erect an addition that will double the capacity of its plant and bring the investment up to \$1,000,000. The company recently became part of the Owens Bottle Machine Company of Toledo, Ohio.

Kansas

KANSAS CITY.—The million-dollar oil refinery and car repair shops to be erected by the Sinclair Oil Corporation will be located in Kansas City, Kan. Work will be rushed on the plant in order to complete it next spring. The pipe line being erected by the company from the Eldorado, Kan., and Cushing, Okla., to Kansas City and Chicago will reach Kansas City by that time.

Kentucky

LOUISVILLE.—The Standard Oil Company of Kentucky will erect a refinery with a capacity of 100,000 bbl. per year on a tract of 336 acres recently acquired.

Louisiana

NEW ORLEANS.—The Freeport Mexican Fuel Oil Corporation plans improvements at the St. Bernard Parish, costing several hundred thousand dollars. W. C. Averill, Jr., is directing the improvements. A new plant will be erected on the Saxonholm property. The company receives its crude oil from Tampico.

Maryland

BALTIMORE.—The Curtis Bay Distilling Company, a subsidiary of the United States Industrial Alcohol Company of New York plans a new plant to handle the by-products from the manufacture of alcohol from molasses. The erection of a mammoth grain elevator at cost \$1,000,000 is also planned, on account of the great increase in ocean freight rates. The present plant of the distillery consists of 12 buildings on a acre of land, directly on the deep-water channel of Curtis Bay. The plant was put in operation last summer. The molasses from which the alcohol is made is brought in tank steamers from Cuba.

LONA CONING.—The Lonaconing Glass Company will rebuild the plant recently destroyed by fire. Citizens subscribed \$23,000 toward the \$100,000 cost of the plant by issuing 6 per cent preferred stock.

Massachusetts

ERVING.—The Erving Paper Mill has recently contracted for the erection of two additions to its plant at Stoneville, near Erving, which will double its capacity. The additions will be completed within one year.

Michigan

DETROIT.—The Pontiac Varnish Company will add two buildings to its plant, thereby doubling its output.

MUSKEGON.—The contract for the erection of the new Brunswick-Balke-Collender Company automobile tire plant, to be constructed within the next sixty days, has been let. The company has already started construction on twenty-four double houses for its workmen.

MUSKEGON.—The Old Montague Iron Works will be rebuilt by a big shipbuilding concern.

Minnesota

ST. PAUL.—Armour & Co. has awarded the contract for driving the piling for foundation of a packing house and subsidiary plants to cost \$50,000.

Missouri

KANSAS CITY.—H. M. Evans and F. H. Thwing have formed a company called the Evans-Thwing Refining Company, with \$1,000,000 capital stock. A site has been purchased in Kansas City for a large refinery, work on which will start at once. This will make the fourth large refinery planned for Kansas City. The Standard Oil Company already has a refinery in operation. The Sinclair Oil Corporation has a refinery at a million dollar plant, and the North American Oil & Refining Company will build a \$250,000 plant.

ST. LOUIS.—The Roxana Petroleum Company will build a 10-in. pipe line from Tulsa, Okla., to St. Louis, and will erect a \$1,000,000 refinery in St. Louis. The Roxana Company is owned by Dutch Shell interests and is a big rival of Standard Oil.

New Jersey

PERTH AMBOY.—A contract has been awarded by the Roessler & Hasslacher Chemical Company for the construction of a \$50,000 building.

WOODBIDGE.—The New Jersey Glue Company will erect an addition to its plant.

New York

ASTORIA, L. I.—The Astoria Light, Heat & Power Company will erect a \$50,000 chemical laboratory at Fifteenth Street and Shore Road.

BROOKLYN.—The National Auline & Chemical Company is building a five-story factory which will cost \$100,000 when finished. The company has a factory on Ross Street and the new plant will be an addition to this, being located along the corner. The structure will be used for essential oils.

NEWBURGH.—The Fabrikoid Works plans the erection of a \$14,000 addition to its plant here.

Ohio

CINCINNATI.—The Charles Boldt Glass Company has let contracts for the construction of a new paper mill and a new factory, each to cost \$250,000. The work will be done by the Ferro Concrete Construction Company.

CLEVELAND.—Reported Carlo-Hydrogen Company, Pittsburgh, will erect factory building and add Hemlock Streets; cost, \$75,000. Tom Knight, 250 The Arcade, is Cleveland agent.

CLEVELAND.—Reported by C. H. Miller, 3317 Broadway Road, will erect foundry 100 x 250 ft.; cost, \$35,000. at State Road and Cleveland Belt Line Railroad.

CLEVELAND.—Reported Riester & Thesmauer, 1512 West Twenty-fifth Street, will erect sheet metal plant; cost, \$300,000. near State Street Road and Cleveland Belt Line Railroad.

MARIETTA.—The Pioneer Window Glass Company, whose plant will be located in Westview, has been incorporated. The officers are Joseph E. Froxy, president; Edward H. Knitzer, secretary, and Leon Laitem, treasurer.

YOUNGSTOWN.—The American Sheet & Pipeplate Company has awarded the contract to the Sharon Clay Products Company for 800,000 bricks to be used in the construction of ten additional hat mills at the Farrell works. The new mills are expected to be completed by next August.

YOUNGSTOWN.—The Republic Iron &

Steel Company plans extensive improvements during the next two or three years, including three additional open-hearth furnaces and an addition to the by-product coke plant.

Oregon

ASTORIA.—The Northern Pacific Brewing plant recently taken by Bruce O. Rowan and J. H. Keating will be remodeled and equipped for condensed milk plant; cost \$100,000.

Pennsylvania

BRISTOL.—Rahn & Haas, of Chicago, will build a chemical plant on the Schaffer farm near Bristol. This will make the second plant for which Bristol has been selected as a location during the last few months. The other is a dye plant to be erected by Daniel Walters.

CARLISLE.—The Mount Holly Paper Mills has been purchased by a Boston concern and will be started up again after being idle for several years. The plant will be enlarged.

JOHNSTOWN.—Directors of the Midvale Steel Company have approved the construction of two blast furnaces at the Cambria Steel Company plant here.

KITTANNING.—The plant of the Kittanning Plate Glass Company, valued at \$1,000,000, has been purchased from the late, by Valentin Neuvert of Kittanning for \$82,000. It is reported that the plant will be renovated and operated to capacity.

PITTSBURGH.—The Western Chemical Company, capitalized at \$25,000, which has been manufacturing dyes in Cleveland for two months will erect a large factory in Pittsburgh. The officers of the company are George H. Fleming, president; J. E. Malone, vice-president, and F. S. Summers, secretary and treasurer. The Cleveland address is 1711 Crawford Road, N. E.

READING.—The Carpenter Steel Works has let the contract for a six-story storage building at 2500th Street.

SCRANTON.—Wilson & Co., meat packers, will erect \$250,000 storage, manufacturing and distributing plant at Millin Avenue and Spruce Street. W. J. Cawley, manager, 7 Dockside Place.

TARENTUM.—The West Penn Steel Company will erect an 80 x 100-ft. addition to its open-hearth department, increasing the capacity of the plant 25 per cent. The company now has four furnaces in operation.

Tennessee

CHATTANOOGA.—The new Chattanooga plant of the Kalkbrenner Corporation is having a new house equipped with Webster Manufacturing Company conveying and elevating machinery.

Texas

HOUSTON.—A company has been formed with headquarters in the Kress Building, Houston, Texas, called the Tidewater Sulphur & Manufacturing Company, to exploit a process for mining sulphur with compressed air. The company owns a tract of 115 acres on Galveston Bay on the Houston Ship Channel, 25 miles from Houston. They claim to have at a depth of 900 ft. a solid bed of sulphur 80 ft. thick. It is proposed to obtain this sulphur by using hot compressed air, under 25 lb. pressure. The compressors are to be run with crude oil, using the exhaust to assist in heating the air, for which purpose the compressed air is passed through heaters utilizing the exhaust gases from the engines and also being equipped with crude oil burners. It is claimed that the air can be heated to 350 deg. Fahr. at a temperature of 100 deg. Fahr. will probably suffice. After leaving the second heater the air passes down into the vein of sulphur through a pipe, inside of which is another pipe. The heated air melts the sulphur and the molten sulphur is drawn up through the inside pipe by a pump and passes into a vat. Work will be commenced on a plant in three or four days. The equipment having already been ordered. It is claimed that the system is cheaper than where steam is used and there is no condensate to bother with. Small plant has been constructed using only 250 ft. of pipe in the air-heating coils and is at present in operation by the Producers Oil Company, of Nabors, La., and is to be used to clean out one of their oil wells. Their former method of cleaning by steam caused a great deal of water to be mixed with the oil. The officers of the company, which is capitalized at \$400,000, are W. R. Britton, president; H. P. Rhodes, vice-president; J. C. Tolman, secretary, and DeWitt C. Dunn, treasurer.

MATAGORDA.—Preparations for the opening of the sulphur field at Big Hill are understood to be nearly completed.

Virginia

PULASKI.—The Pulaski Foundry & Manufacturing Corporation, which recently increased its capital from \$25,000 to \$50,000 will use this capital in enlarging its works.

Washington

LA GRANDE.—The American Nitrogen Products Company, Securities Building, Seattle, has closed a contract with the Tacoma municipal electric system for energy to operate the first unit of its plant, which it is erecting at La Grande, at a cost of about \$300,000. The company filed water rights on the Snake-Salt Lake River, 50 miles north of Everett, several years ago, and intended to build its plant there, but pending the decision of the Seattle municipal lighting department as to the advisability of the site for municipal power purposes, decided not to wait until the city of Seattle had waived its claim to the power site.

TACOMA.—Several million dollars worth of improvements are being completed at the Tacoma plant of the American Smelting & Refining Company. They are now building a new refinery, have just completed a new power house and are now building a new brick house and quarters for the men.

SEATTLE.—The American Nitrogen Products Company, capitalized at \$500,000 is building a small plant for the fixation of nitrogen from the air. The company proposes ultimately to build a large permanent factory on the Sauk-Salt Lake River in Snohomish and Skagit counties. C. Craft of Seattle is president of the company and the directors include: Dr. I. Jansen, Dr. A. O. Lee, and C. Nasten.

PORT ANGELES.—An agreement has been made between Whalen Bros. of Mills Creek, B. C., and E. C. and S. S. Francisco, president of the Puget Sound Mills & Timber Company of Port Angeles, whereby the latter will furnish raw material to operate a paper plant. The first unit to be erected will produce 60 tons daily; the whole plant ultimately costing \$750,000.

West Virginia

FAIRMONT.—West Virginia newspaper publishers have been considering the advisability of establishing a paper mill to supply the newsprint for this state. A meeting was held in Fairmont at which committees were appointed to report at a meeting in Parkersburg in January. J. J. Levine of the Telegram at Clarksburg, presided.

Wisconsin

MANITOWOC.—Plans for erection of a large rolling mill in connection with the plant of the Aluminum Goods Manufacturing Company in this city are under consideration, according to President George Vits.

MENASHA.—The Gilbert Paper Company is erecting a large addition to its mill on the South Bank of the Fox River. It will be used for water supply tanks and filters.

Canada

TRAIL, B. C.—The Consolidated Mining & Smelting Company of Canada will increase the capacity of its copper refinery at Trail to 15 tons per day. The company supplies the own blister copper as well as that from the British Columbia Copper Company's smelter at Greenwood, B. C.

WELLAND, ONT.—Contract awarded by Canadian Steel Foundries, Ltd., Ontario, to Ryan & Co., Ontario, for erecting brick and steel addition to plant; cost \$150,000.

Manufacturers' Notes

GAS SHORTAGE IN OHIO.—Glass plants in Sandusky, Ohio, have established their own gas producing plants and no longer have to depend upon the supply of natural gas. They are now able to operate at all times and have an advantage over other glass manufacturers who are now so much depended upon and where there is a shortage.

BAKELITE COMPANY MOVES.—The new address of the General Bakelite Company is No. 8 Borden Building, New York City. The new location larger and better arranged offices materially assist in handling the increasing business.

CHEMICAL PLANTS MUST GET PERMITS.—Chemical plants in the Belleville district along the Passaic River were required to obtain permits from the Board of Health to operate owing to the discovery of a section in the sanitary code by the health officers. The Belleville Metal & Chemical Co., The Edison plant at Silver

Lake and Eastwood Chemical Company and several other concerns are affected.

SUBSTITUTE FOR AMYL ACETATE.—A substitute for Amyl Acetate in the manufacture of aerolite products has been brought out recently by Albert L. Kraus of the Kraus-Millett Co., of Portsmouth, N. H. The new solvent it is claimed fulfills every necessary requirement of the more expensive amyl.

AMERICAN COMPANIES IN CANADA.—Since the outbreak of the European war about fifty American companies have established branch plants in Canada, the cost of which is estimated at \$15,000,000. Prior to the war there were 450 American companies with branch plants in Canada, and the present plant investment represents \$15,000,000. Some of the articles manufactured in Canada by American companies recently located there are as follows:

Railway accessories, overalls, chemicals, silverware and flatware, automobiles, horse-shoes, steel goods, patent medicines, spices, fragrances, perfume, glue, beet sugar, blue-greenhouses, railway signals, fuses, boxes, spreaders, silk gloves, stockings, tires, steel and pulp products, canned goods, automobile varnishes, beet sugar, blue-greenhouses, pulp and paper, sewing machines, aloxite and other abrasives and electric furnace products, grain and elevator machinery, silk and chamois, rubber goods, refined nickel, and cottonseed oil products.

GOVERNMENT NITRATE PLANT.—Congressman Longworth of Cincinnati has introduced a bill repealing the act which authorized the erection of a \$20,000,000 government nitrate plant.

WATKINS WEBSTER SELLS AIR CONDITIONING SYSTEMS.—The Warren Webster & Company of Camden, New Jersey, announces that they have disposed of the business of their air conditioning department, and on and after January 1, 1917, the Webster air conditioning apparatus will be manufactured and exploited by the Braemar Air Conditioning Corporation, Lafayette Building, Philadelphia, Pa.

EAST SHORE AREA AFFECTING PENNSYLVANIA MILLS.—The mills in the Monongahela Valley have been hindered by a shortage in gas and several had to shut down for a time during the first of December, including The Macbeth-Evans Glass Co., The Donora Mills, The United Glass Works and The Pittsburgh Steel Foundry. Officials of gas companies explained that the domestic demand was so great that it was necessary to reduce the supply to mills. The large mills are hurrying work on new fuel systems.

FILTER PRESSES.—The Newport Chemical Works, Inc. of Milwaukee, have placed an order with D. R. Sperry & Co., Batavia, Ill., for presses for filtering wood and iron construction, for their new Carrollville, Wis., plant. These presses will be in the manufacture of dyes.

ELEVATING AND CONVEYING SYSTEMS.—The Webster Manufacturing Company of Tiffin, Ohio, are installing a complete elevating and conveying system in the new extension of the Portland Cement Company, Ironton, Ohio, and a conveying and transmission system at the National Phosphate Fertilizer Company, at Centerville, Tenn., for handling the phosphates.

AUSTRALIAN MARKET FOR CHEMICALS.—Advices have been received from Richmond, Australia that there is a market for calcium, magnesium sulphur and zinc chloride, compressed chlorine and antimony sulphide in Australia.

DISC CRUSHERS.—Chalmers & Williams, Chicago, Ill., Highland, Ill., has recently installed four Symons 48 in. vertical disc crushers. At the Federal Lead Co., Flat River, Mo., two at the Burro Mountain Copper Co., Chiquita, Ariz., six at the Chib. Exploration Co., Chiquita, Ariz., and two at the Calumet & Arizona Mining Co.

DIE-CASTING COMPANY ADOPTS PROFIT SHARING.—A complimentary dinner Dec. 15, tendered to the Doehler Executive Club, which is composed of all the executive heads of the Doehler Die-Casting Co., with factories at Highland, N. Y., Newark, N. J., and Toledo, Ohio, the following announcement was made by Mr. H. H. Doehler, its President and General Manager:

To the employees of the Doehler Die-Casting Co. of Brooklyn, Toledo and Newark.

The Doehler Die-Casting Co. realizes the increasing cost of living. To assist our workers to meet these new conditions and at the same time to reward our loyal workers, we offer to all our employees the following inducements in the form of an extra participating dividend on their wages.

Beginning January 1, 1917, whenever this company declares the regular dividend on their stock it will also declare a wage dividend amounting to 10 per cent per annum to all employees based on all wages actually received including piece work and

overtime. This wage dividend is subject to the following conditions.

1. An employee must be in our employ before interruption for a full year before he can participate in the wage dividend. Upon completion of a full year's employment he automatically becomes a candidate for this wage-dividend. His wage-dividend will be calculated from the date of completing the first year's employment to the date of declaration of dividend.

2. This wage dividend when declared will be apportioned in the following manner:

First—Will be paid in full to all employees who have been in our employ for a full period of three years or more.

Second—Will be paid in full to all employees who have been in our employ for a full period of two years and less than three years.

Third—One-third will be paid to all employees who have been in our employ for a full period of one year and less than two. This wage-dividend will be declared quarterly the same as our stock dividend.

It was further announced that beginning Jan. 1, 1917, all employees who have been working on the basis of 50 hours per week will be put on a basis of 48 hours per week at the same pay, believing as Mr. Doehler said, that 8 hours per day was sufficient for all men who work. This company employs 1,200 men, and has a weekly payroll of approximately \$25,000.

New Manufacturers' Publications

"Arc Welding." A booklet prepared by the Arc Welding Machine Co., Inc., 220 West Forty-second St., New York. Describes the company's new Electrodeless Arc Welding and gives general theory of arc welding.

The Prest-O-Lite Co., Inc., Indianapolis, Ind., has issued an instruction book for lead burning with oxy-acetylene. In the introduction it is stated that the term "lead burning" is somewhat misleading, as the work performed by this process should more properly be termed oxy-acetylene welding. The process has however come into common use. The process is not confined to work in lead but can also be used on tin and other low melting point metals or alloys. The book gives a description of the Prest-O-Lite Outfit and directions for burning sheet lead, storage battery work, joining lead and other pipe, making tees, etc.

Chicago Pneumatic Tool Company, Chicago, Ill., Bulletin E-15, superseding E-40 and describing Duntley portable electric hoists.

Chicago Pneumatic Tool Company, Chicago, Ill., Bulletin 129 describing hose, hose couplings and hose clamps.

Schweitzer & Conrad, Inc., Bulletin 1A, describing S & C extra-high-potential fuses.

Aero-Engine Co., Inc., Bulletin 2, describing pulverizing fuel. Bulletin 25, discussing the advisability of pre-drying coal before burning.

Armstrong Cork Company, Pittsburgh, Pa., "Nonpareil Corkboard Insulation for Cold Storage Rooms" and "Fifteen Years on Brine Lines," the latter describing a service test.

The Mine and Smelter Supply Company, Denver, Colo., Bulletin 34, describing the Lindsay oil burning assay furnaces and oil burners for schools and college agents.

The furnaces and burners are manufactured by The Colorado Crucible and Clay Company.

The Mine & Smelter Supply Company, Denver, Colo., Bulletin describing the Tresser analytical and assay balances with multiple weight attachments, and various accessories.

American Blower Company, Detroit, Mich., Bulletin 13, Series 9, superseding No. 345, and describing Type D and Cyclone Dust Ventilating Fans.

Galvanometer Fans.—Pyroelectric Instrument Company, Trenton, N. J., Circular No. 2, describing galvanometers Ayton shunts, Pyrocommutator and dial resistance dea boxes.

Janney, Steinmetz & Co., Phila., Pa., has issued a bulletin describing "Jasco" seamless heavy retort ware, pots, pans, ink buckets, tanks, etc.

Golden-Anderson Valve Specialty Company, Fulton Bldg., Pittsburgh, Bulletin describing Golden-Anderson automatic valves for protecting steam and water lines.

The Brown Holsting Machinery Company, Cleveland, Ohio, has just put out an attractive catalog of 1917, showing some interesting photographs of underground operations with Brown apparatus at various ore and coal docks, and loading operations on railroad cars.

Chicago Pneumatic Tool Company, Chicago, Ill., has issued Bulletin 34-W, describing "Grant" fuel oil engines.

The Motor Equipment Company of Minneapolis, Minn., has issued a pamphlet describing its vertical alternator for use in small and medium sized hydro-electric plants. The generator is direct connected to a vertical waterwheel shaft, eliminating all grass, belt, rope drives, etc. The weight of the waterwheel and the downward thrust, as well as the revolving parts of the generator, are carried on a roller thrust bearing submerged in oil. It is claimed that these alternators are much more efficient than a gear or belt driven machine.

Handbook of Westinghouse Watt-hour Meters, issued by Westinghouse Electric & Manufacturing Co., East Pittsburgh, Pa. Gives the early development of watt hour meters, details of Westinghouse meters, constants and test formulas, use of standards and other important details.

Other New Publications

"Facts About Water Power," Prepared by the executive committee of the Water Power Development Association, Munsey Bldg., Washington, D. C. Gives the available water powers, development and development, and shows the demand for further development under adequate laws.

"Production of Iron and Steel in Canada in 1915," by John A. McLean, of the Division of Mineral Resources and Statistics. Published by the Department of Mines of Canada, Ottawa.

Gold, Silver, Copper, Lead and Zinc in Mexico and Texas in 1915," By Charles W. Henderson. Geological Survey Report, Washington, D. C.

"Freezing Point of Mercury," By R. M. Wilhelm. Bulletin, Paper No. 24, of Bureau of Standards. The paper gives results of a determination of the freezing point of mercury using platinum resistance thermometers, and shows the temperature.

Failure of Brass 2.—Effect of Corrosion on the Ductility and Strength of Brass. By Paul D. Merica. Technologic Paper No. 83 of Bureau of Standards.

Failure of Brass 3.—Initial Stress Produced by the Burning In of Manganese Bronze. By Paul D. Merica and C. P. Karr. Technologic Paper No. 84 of Bureau of Standards.

Gold, Silver, Copper, Lead and Zinc in Utah in 1915. By V. C. Heikes. Geological Survey Report.

Government Ownership and Regulation.—Bulletin of Merchants Association of New York, opposing government ownership and operation of public utilities and advocating exclusive regulation of all railroads by the Federal government.

Gold, Silver, Copper, Lead and Zinc in Montana in 1915. By C. V. Heikes, U. S. Geological Survey Report. Mineral Resources of the U. S.

Gold, Silver, Copper, Lead and Zinc in Arizona in 1915. By C. V. Heikes, U. S. Geological Survey Report. Mineral Resources of the U. S.

Annual Report of The Federal Trade Commission. For the year ending June 30, 1916. Government Printing Office, Washington, D. C.

"Practical Handling of Iowa Clays." By Homer F. Staley and Milton F. Beecher. Bulletin 43 of the Engineering Experiment Station at Iowa State College of Agriculture and Mechanic Arts.

Oil Shale in Northwestern Colorado and Adjacent Areas. By Dean E. Winchester. Geological Survey Bulletin 647. Contains information showing that when certain conditions justify it, these Colorado shales can be distilled yielding large quantities of oil and gas, and furnishing nitrogenous by-products for fertilizer.

National Tank & Pipe Co., Portland, Oregon, has issued catalog 14, describing with illustrations and technical details tanks, crossarm silos and steam pipe fittings, and other specialties and giving new tables and information on pipe not heretofore published.

The Federal Trade Commission has issued in two volumes a report on co-operation in American Export Trade being the results of investigations made by the Federal Trade Commission.

Vapor Pressure Measurements.—"Vapor Pressures of Various Compounds at Low Temperatures" is the title of Bureau of Mines Technical Paper No. 42. By G. A. Burrell and I. W. Robertson. The paper gives the results of measurements on ethane, ethane, propane, propylene, butane, acetylene, ammonia, sulphur dioxide and nitrous oxide.

A Study of Oil Engines in Iowa Power Plants. By H. W. Wagner. Bulletin 42 of Engineering Experiment Station at Iowa State College of Agriculture and Mechanic Arts.

Gold, Silver, Copper, Lead and Zinc in Colorado in 1915. By Charles W. Henderson. Geological Survey Report. Part of Mineral Resources of U. S.

Metallurgical and Chemical Engineering

A Riot of Organization

"Organization," says H. G. Wells in an essay lately published, "is the life of material and the death of mental and spiritual processes." That is one of those observations that holds true from one angle of vision and is clearly false from another. If we were to say that organization as an end, rather than as a means to an end, kills mental and spiritual processes, there would be few to contradict it. And despite the chaotic state of chemical industry in this country to-day, and the need of organization right and left, it is worth while to remember that over-organization is as bad as disorder.

Nearly every one of us has some little trick that he can perform better than he can do other things, and there is good advice from all grades of intelligence, from genius to orthodoxy, to the effect that we should conserve our talents. But if we were so organized that each of us were under compulsion to repeat his one little trick, over and over again, the livelong day, we should lose in imagination what we should gain in efficiency.

Francis Hackett, whose wit is sharper than everybody can see, lately proposed that eugenics be employed to breed a race of efficient industrial workers who shall be strong, healthy, good-natured and exceedingly dull. In short, he proposes (in satire) a race of morons, of feeble-minded but strong-bodied workers, for efficiency. But the fact is, there are in process of breeding feeble-minded in vast number, and the great task is, as we have said before, to find employment for them. Since manufacturers will not have them if they can help it, the labor unions have had to take them on and slow down their gait to meet the limitations of their dull and incompetent members. The organization of the feeble-minded along with whole men, lest the weak ones starve, is one of the leading reasons why collective bargaining with labor unions is so difficult.

We have in mind a great works the pot-bellied authorities of which point with pride to the speed with which their hands are able to do the same task over and over again throughout the long days and weeks and months and years. The error lies in the belief that the monotony of speed at one task will be profitable throughout the years. They are putting whole men at work designed for the feeble of wit, and just as depreciated currency returns to its source, so the mentally helpless will drift to the jobs designed for them. And good men will degenerate or go away.

Now as many useful ideas emanate from the shop as from the drafting room, and if the men in the shop work as machines rather than as men, or with

their minds asleep, the output may not go down, but somebody else will soon come along with something better.

We can organize the life out of factory practice, and thus cause a waste of men and of ideas on the one hand that is more dangerous than the waste of material and time that comes from the lack of organization.

Economies in Steel Manufacture

The steel industry has always been crying for more capital. When the Payne-Aldrich tariff was under advisement a number of steel manufacturers went down to Washington and asserted that the only way to make money in the steel industry was by selling out. The statement was calculated as a rejoinder to Mr. Carnegie's testimony to the effect that the steel industry did not need protection. Mr. Carnegie was rich—but he had sold out! There was a large element of truth in the statement, however. One could make money in the steel business, perhaps, but he could not take it out; he could not "cash in." There was always the necessity of spending the earnings.

For the first time in the history of the American steel trade there are earnings so large that there is no occasion to spend the major portion of them in plant extensions, in order that each one may keep pace with his neighbor and nobody fall behind. It is impossible, indeed, to spend the major part of the money because there are not enough workmen and makers of supplies, equipment, etc., willing to accept the money. There is a large works extension program being carried out, but it is not absorbing the profits nearly as fast as they are being made. All the improvements made in this expansive movement, which began about the middle of 1915, and all still to be made, would only total in the neighborhood, probably, of \$300,000,000 to \$400,000,000, or perhaps a trifle less than the surplus earnings to date, beyond all charges and the ordinary dividend requirements. There are still large earnings in prospect.

The new construction program, however, is regarded in the trade as very nearly a finality as regards increase in tonnage output. Further improvements that may be made will be in the direction of introducing still greater economies in manufacture, partly by way of saving money on the cost sheet and partly by way of making new products, carrying the steel to a greater degree of finish, and making by-products, of which there may be many apart from the well recognized by-product of the retort coke oven.

As to these refinements the steel industry is in no hurry. Most of them cannot well be undertaken when works are being driven to produce the last ton of steel possible, or when labor and supplies are scarce. The time will come for them in due course.

Of the refinements that are to be considered the further reduction in labor must stand prominent, from both the social and the economic viewpoint. The 12-hour day really has no friends, those who are its sponsors merely considering it a necessity in the circumstances. The iron and steel industry's labor has been

supplied largely by immigration. During the two fiscal years before the war the increase in population of the United States, due to excess of arrivals over departures, averaged 50,000 a month. Since the war started the increase has been light and what may be called a deficiency, having regard to the previous rate, has accumulated to the extent of more than 1,000,000. After the war there will hardly be much of an influx of able-bodied men such as could be recruited into the industry. With a lessened supply of labor in proportion to the industry's growth and with a tendency to shorten the hours of labor the unskilled labor must be displaced more and more by machinery, and the industry will not find itself, as it occasionally has in the past, with neither the money to pay the men nor the money to buy the machinery with which to replace them.

By-Product Coke

A function, if not a use, has been found for the beehive coke oven, to take the peak off the load. According to the estimate just made by the Geological Survey coke production in 1916 was about 19,200,000 net tons by the by-product process and 35,100,000 tons by the beehive oven, making a total of 54,300,000 tons. Although the increase in by-product coke from 1915 to 1916 was 36 per cent, the increase in the proportion of by-product to total coke was only from 34 to 35 per cent. The production of beehive coke had "come back" under stress of demand so that the year's tonnage was substantially equal to the record tonnage, made in 1907, when it constituted 86 per cent of the total output. In the intermediate years the tonnage was much less.

The demand for coke, inasmuch as 80 per cent of the total output, on an average, is used in the manufacture of pig iron, fluctuates widely. By reason of the large investment involved in by-product ovens it is desirable that they should operate with a fair degree of continuity, and it will be convenient to have the beehive ovens to fall back upon at times, to eke out when there is an extraordinary demand.

By-product coking practice, in the latest developments, has been kinder to the beehive coking coal fields than was expected. The wind has been tempered to the shorn lamb. In recent years there has been a trend toward larger proportions of the coals hitherto used in beehive practice than had been anticipated, and thus the beehive operations can continue, by shipping their coal to by-product ovens, and in times of stress increasing their coal output and coking the excess in their old beehive ovens.

The number of by-product ovens completed at the beginning of this year has not yet been reported, but the number on January 1, 1916, was recently reported at 6268, and the number since completed, or now under construction, will bring the total to about 9000 retorts. The actual statistics of production do not reflect the outputs claimed possible with ovens as now built, but the newer ovens will doubtless do better. Giving the retort the benefit of the doubt, and assuming that only those completed by the beginning of a year contributed

to the year's output, the average output per retort has been, according to the Geological Survey's reports: 1912, 2400 tons; 1913, 2440 tons; 1914, 2130 tons; 1915, 2430 tons; 1916, 3050 tons. Most of these years were years of substantially full operation.

In the circumstances it seems perfectly safe to predict that the ovens now built and those being built will have a capacity of fully 30,000,000 net tons of coke per annum. When the blast furnaces now being built are completed the total pig iron capacity will be close to 45,000,000 tons a year, requiring in the neighborhood, according to the experience of 1915, about 50,000,000 tons of coke a year. Thus there is still much room for growth in the by-product coke industry.

Laziness, Efficiency and the Efficient Laziness

In Mark Twain's classic we find that the youthful hero "Tom Sawyer" had on a Saturday the hard job of whitewashing a fence thirty yards long and nine feet high. His thoughts wandered to the swimming hole. He was feeling just so "plum lazy" that he did not like the appalling task. So he thought, as the real prototype of the modern efficiency that he would use his head rather than his hands, and accordingly placed his job before his friends in the pleasing light of that of a noble craftsman. We all know the sequel: He got his pals to pay for the privilege of doing his work for him and he arrived at "the efficient laziness."

Now, laziness with us has an unpleasant connotation suggestive of the "bum," and usually means the disinclination to do honest work of any kind. But it can carry the further meaning of the disinclination to do any unnecessary work and of the desire to get machinery to perform the work and not waste energy. We believe that from the all-pervasive human tendency to do no work, or at least a minimum of work, perforce is born the inventive instinct, and in this secondary meaning of laziness there is a lesson. From the lazy notion that the unloading of dirt from a cart was hard work came the dump-cart. The disinclination to delve, developed the plough. A tread-mill is a poor prime-mover—hard, laborious effort of man or beast produces only a few foot-pounds per minute. But Watts made the stored-up sunlight of ages produce the equivalent of many men and horses. Doubtless, the steady grind of the tread-mill is good to an extent for both man and beast, but it is not elevating to them, either in a spiritual or in a physical sense. And the intelligent way was for man to develop some other prime-mover. The waterwheel turning round absorbs the potential energy of stored water. The old "overshot" wheel spilled and splashed round water, but was very inefficient. It made a fine show and was "beautiful," but it was not useful. A modern large turbine discharges its water in a slow and lazy stream into the tailrace and is efficient. The lazy man "cuts off" his steam and allows it to expand as happens in a Corliss engine.

Noise and splash are signs of activity, but not of intelligent activity. They show wasted effort. In all human endeavor, there is the attempt to perform the minimum effort and to produce the maximum result.

This is not exactly what we usually call laziness, but it surely is closely allied to laziness in its general meaning and it is "the efficient laziness." A lazy man is naturally graceful. He is so "darned lazy" that he will make no unnecessary motion and moves with languid ease and grace. He is not over-anxious or too eager. He does not slop over or waste his energy for he prizes energy so highly that he uses every bit of it. Impelled by the thought that he must live, he develops his intelligence and moves along the line of least resistance. To get out of doing hard work, he will devise and use levers, cams, electromagnets, relays, belts, clutches and gears. All these are born of the innate desire of man to escape effort, and out of this situation intelligence arises to give birth to expedients and other means to escape drudgery.

Just as the most beautiful flower, the rose, grows out of animal corruption, so does intelligence grow out of laziness.

Now, of course, there must be energy of some kind as the impelling force and without energy nothing can proceed, for the rationale of energy lies in its utilization. The command of nature is that energy must not be wasted by man. The prizefighter who spars with rigid muscles is quickly worsted by his antagonist who moves relaxed except at intervals of intense effort. The long-distance runner goes on his pace with a graceful lope if he is to be the winner. Whereas his competitor runner who bounces up on the muscle of his calves soon exhausts himself and an excess of uncontrolled energy is the cause of that great American malady, "nervousness." No lazy man fidgets.

Indeed, an intelligent and efficient laziness is the greatest of America's needs. "Pep," "punch" and "kick" are fine national assets, but to be using them continually soon dulls their edge and wastes them. Observe if you will the wild animals who have no consciousness to arouse them to pernicious activity. When they lie down, they are relaxed. When they move slow they move with a lazy motion. There is no living creature more efficiently lazy than the lion. When he moves fast he moves with no lost motion, and with a magnificent spring. He is the great unconscious engineer.

Engineering and invention proceed from laziness. Is there anything more conducive of laziness than the "slide rule?" So, then, while laziness, like manure, is not always pleasant and should be put under the ground out of sight, a clear understanding of the proper use of this supposedly smelly and not always agreeable human quality will help the chemist and engineer, but not if carried to the point of self-deceit. For laziness if unintelligent brings forth self-deceit. This, however, is not "the efficient laziness."

The efficient lazy man is the apogee of the sine-curve of intelligence. When he toils, he spins.

The stock proverb on this subject we know was "Go to the ant, thou sluggard, consider her ways and be wise." Should it not be, "Go to the sluggard, thou ant, consider her ways and be efficiently lazy." "Be sure when you nip the aphid-worm that you use only three nips, instead of the five that you have been using."

A Personal Note

To the Editor of Metallurgical & Chemical Engineering

SIR:—With your permission, the undersigned would like to make public the fact that the "J. W. Richards" endorsing circulars recently issued exploiting Mr. Sydney J. Jennings for president of the American Institute of Mining Engineers, is Mr. John W. Richards of Denver, and not Dr. Joseph W. Richards, vice-president of the Institute and chairman of its Iron and Steel Committee.

JOSEPH W. RICHARDS.

Lehigh University.

Our Wasting Water Powers

To the Editor of Metallurgical & Chemical Engineering

SIR:—Your journal is right in drawing again and again attention to the enormous importance of the water-power problem at Niagara and elsewhere at the present time.

Through a long course of legislative fatuousness our country has lost millions of dollars in wasted power, and stands to lose many millions more unless the present situation is remedied. The fundamental economic principle about hydraulic power is that every cubic foot of water that plunges downward unutilized is a sheer waste of inherent national wealth. If you do not dig up your coal or cut down your wood its fuel value remains, while in the case of unused water powers the water of the present runs to absolute waste. All the value which it represents is as completely lost as if it were T N T exploded at the front with the amiable intent of blowing a few fellow mortals off the earth.

When a country is only partly settled and manufacture is a casual rather than a vital industry the neglect of hydraulic privileges represents less immediate and serious loss, but as the nation's industrial resources are more and more thoroughly developed and particularly as electrochemical processes have come to take a greater and greater part in the economic result, neglected powers are more than regrettable, they are disastrous. Electrochemical works require plentiful and cheap power such as can be obtained only by the utilization on a big scale of the big streams, even navigable streams, as well as others in the public domain. And how great a part electrochemical processes play in manufacture apparently only remotely related to them your journal is continually pointing out.

The fullest possible power supply obtained within the shortest possible time is the fundamental requirement for that complete organization of American industry which is necessary to the prosperity of the nation now, and will be even more vital within the next few years. It is up to Congress to show some signs of patriotism and human intelligence instead of playing politics and talking buncombe in the effort to disconcert an alleged water power trust that does not exist. It is not remarkable that far-sighted folk should be interested in the development of water powers, and the movement toward this end is as spontaneous as hunting after any other article of well-known and established value.

Those who oppose hydraulic development fall into three categories: First, come the narrow-minded souls who shudder with fear lest somebody else make a dollar by judicious investment; second, that amiable group

of socialistic proclivities, who want the Government to screw enough out of each projected enterprise to wreck it as a business proposition; and third, come the long-haired and mild-eyed sentimentalists who whine about dangers to the beauties of Niagara—for the last half century a dismal congeries of cheap hotels, boarding houses, bawling cabbies and open-mouthed bridal couples. The sentimental value of a great cataract is is not unworthy of consideration, but this particular one had lost all esthetic importance before the first power plant burrowed its tail-race through the cliffs.

The thing of vital importance to the country at the present time is that all the sources of hydraulic power which are economically available should be brought quickly into use so as to give modern industry a fair chance. The water which is not used to-day is lost capital. We need water power legislation which shall give encouragement toward the immediate development of every horsepower worth the while, with provision to protect the government in its ownership if you like, by regulation of prices and by limitation of charter rights, but constructive instead of destructive as at present.

It must be remembered that the most promising of such enterprises are big ones not to be carried out by a small investment and in a single season. They require large amounts of capital which can be had cheaply if reasonable security for its investment can be granted. Time, too, is required so that if two or three years from now there is to be cheap power for the multifarious uses men find for it, a beginning must be made at once.

Public service enterprises such as these do not resent reasonable supervision. They have on the contrary learned to expect it, but they cannot exist in the face of uncertainty with respect to reasonable profits and tolerable continuity of business. The tendency of legislation seems to be to cultivate uncertainty and to leave the would-be investor quite in the dark as to whether his property will be his own a few years from now or will have been in some way benevolently assimilated by the powers that be.

The important thing for far-sighted legislators to realize now is that the thing at stake has to do with the conditions of permanent prosperity as respects many of the country's big industries. It is a question of substituting frugality for waste, of building up instead of tearing down, of looking to the benefits of the future instead of whining over the peccadillos of the past.

The Recovery of Chinchonine from Any Solutions in Which It Is Used to Remove the Last Traces of Tungsten

To the Editor of Metallurgical & Chemical Engineering

SIR:—Owing to the great advance in price and the difficulty encountered trying to procure chinchonine for the determination of tungsten, the writer has been using the following method to recover this reagent from filtrates in which it has been used.

Place the waste filtrates which contain the chinchonine into a suitable container until 5 or 10 gal. have accumulated. To this solution add slowly and with constant stirring a strong solution of commercial caustic soda until the solution is just slightly acid. When this

point is reached add an emulsion of zinc oxide until all the iron, etc., is precipitated. If when this point is reached the precipitate seems too thick so that no clear solution shows at the top, then add several liters of tap water and allow the precipitate to settle.

When the precipitate has entirely settled, decant off the clear solution. To this clear solution add ammonium hydroxide, having enough in excess to redissolve any zinc which might precipitate. The amount of ammonium hydroxide needed here will depend on the amount of zinc oxide needed to precipitate the iron, etc. If the solution was brought close enough to the neutral with caustic then the amount of zinc oxide will be smaller and it will not require such a large excess of ammonium hydroxide. Of course, if some zinc is precipitated with the cinchonine at this point it will not matter so much as it will be removed later during the process of purification. The only thing that the zinc does here is to retard filtration of the cinchonine.

When the ammoniacal solution is obtained it will also contain a grayish white precipitate of the impure cinchonine. Filter off this precipitate, using a Buchner funnel and suction. Wash the precipitate several times with hot water, suck dry and then dissolve the precipitate from the filter with hot (1-1) hydrochloric acid, washing the filter several times. This acid will dissolve the precipitate from the paper. To this solution add some tartaric acid and again make ammoniacal, a white precipitate of cinchonine should be obtained. This precipitate is filtered off and thoroughly washed with hot water, dried at 105 deg. C., and bottled for use in making cinchonine solutions.

The precipitate of iron from which the clear solution was decanted in the first place is stirred up and tap water added and the precipitate again allowed to settle and this clear solution again drawn off and the cinchonine recovered from this as explained. By making several decantations of this kind it has been able to recover at least 90 per cent of the cinchonine.

The filtrate from the purification of the first precipitate of the cinchonine is saved and used to precipitate the cinchonine from the second decantation from the iron precipitate. In this way a saving on the amount of ammonium hydroxide needed can be made.

Coming Meetings and Events

Society of Chemical Industry, New York Section, Perkin Medal Award, New York, Jan. 19, 1917.

Joint meeting, New York Sections, American Electrochemical Society and American Institute of Mining Engineers. Machinery Club, New York, Jan. 26, 1917.

Joint meeting of New York Section of American Electrochemical Society, American Chemical Society and Society of Chemical Industry, Rumford Hall, Chemists' Club, New York, Feb. 9, 1917.

American Institute of Mining Engineers, annual meeting, New York, Feb. 19-22, 1917.

Meeting of New York Sections of American Electrochemical Society and American Institute of Mining Engineers

A joint meeting will be held on Friday evening, Jan. 26, by the New York Sections of the American Electrochemical Society and the American Institute of Mining Engineers. The topic of the evening will be "The Electrical Precipitation of Smoke and Dust." It will be a dinner meeting (charge \$1.75, including drinks), and will be held at the Machinery Club, 50 Church Street, at 6.30 p. m. Messrs. Linn Bradley, W. W. Strong and A. F. Johnson will speak.

Western Metallurgical and Chemical Field

Gasoline from Oil Shales

A great deal of interest has of late been shown in various parts of the world in connection with the extraction of gasoline from shales rich in hydrocarbons. It is not impossible that in future, due to the advancing cost of gasoline from petroleum, means may be sought from which this much demanded product can be produced independent of the oil syndicate.

For three years the U. S. Geological Survey has investigated these deposits, the largest of which are found in the Green River formation of northwestern Colorado and northeastern Utah. These areas have been mapped out, their depths and length have been measured, and crude field tests have been made along the lines of distillation. The shales on distilling yield petroleum, the amount depending largely on the richness in hydrocarbons of the shales, which varies in different localities.

In the United States Geological Survey Press Bulletin for December, 1916, it is stated that 20,000,000,000 barrels of crude oil could be obtained by distilling such shale deposits ranging over 3 ft. in thickness in Colorado alone. This would yield in the neighborhood of 2,000,000,000 barrels of gasoline, an item of considerable importance. At present the Bureau has in press a report giving the results of the exploration, the tests made on the shales and an account of experiments made to determine the possible gasoline production, both by the ordinary commercial processes and by the Rittman process. This report should prove of great interest to gasoline producers and users.

The oil produced from some of these shales is dark brown in color, rather mobile, and has a dominant odor of the lighter hydrocarbons. The extent to which these latter are present may be judged from a sample kept in the writer's office. On receiving that sample directly from the source of distillation, it was put in a bottle and stoppered very tightly with an ordinary cork. After standing for three weeks the oil had become very viscous, had very little odor due to the lighter hydrocarbons, the main odor now being that typical of the product left on distilling ordinary petroleum for the lighter and more volatile constituents. This certainly seems to indicate that the percentage of volatile constituents is very high, which is a promising asset for the production of gasoline.

South Africa seems to offer another possible source for gasoline from bituminous shales. According to the *South African Mining Journal*, Aug. 19, 1916, page 460, such bituminous shales should not occur in metamorphic rocks, because any severe metamorphism destroys these shales. Bituminous shales are known to occur in the Black Shale group in Rhodesia. This deposit lies in the region of the Wankie Main coal fields. Other possible localities in South Africa are the main belt which stretches in a northeastern and southwestern direction through the Wankie and Sebungwe districts. This belt in the northwest expands and includes most of the country between the Great Escarpment and the Zambesi River, the northernmost portions of the Lomagundi district, the Sabi coal field in the Ndanga district and the Umzingwane and Massabi fields in the Gwanda district. An interesting article on the occurrence of oil shales in Natal is found in the Oct. 28, 1916, number of the *South African Mining Journal*, by Alexander L. du Toit. Du Toit states that he has examined shales which produced 27.1 gal. of crude oil per ton of shale. On the other hand, reports have it that shales giving a far greater amount of crude oil have been tested.

Some general information regarding these shales may be of interest. Rich oil shale is very tough, burns on ignition and resists, to a remarkable extent, erosion.

On weathering these shales take on a bluish white color. A good oil shale should be dense in structure and flatten out to an adhering mass on pressing a small piece with the blade of a knife.

An item of interest in this country is that the Colorado oil shales yield a crude oil which gives 10 to 15 per cent gasoline by ordinary methods of refining. Furthermore, with little more investment 300,000,000 tons of ammonium sulphate could be derived from the Colorado shales. This product is of exceptional value as a fertilizer. The equipment for a plant handling these shales would be rather high, and comprise buildings, retorts, condensers, refining machinery and mining machinery. As in many other industries, the oil shale industry on a small scale would in all probability not pay.

Company Reports

The annual report of the *Buffalo Mines, Ltd.*, for the period commencing with May 1, 1915, and ending with April 30, 1916, shows that the mill treated 38,157 tons. Of this 30,079 tons were treated by wet concentration, averaging 19.8 ounces of silver per ton, with a recovery of 431,512 ounces, and 8078 tons were treated by combination concentration and oil flotation, averaging 25.46 ounces of silver per ton, with a recovery of 197,601 ounces. The cyanide plant treated 6340 tons of slime from the concentrator, averaging 10.54 ounces of silver per ton, of which 55,161 ounces were recovered. The total silver recovery by mill and cyanide was 684,274 ounces.

The amalgamation plant and refinery treated 13,465 lb. of high-grade directly from the mine, 285,554 lb. jig concentrates, 718,240 lb. table concentrates, 1952 lb. of metallics from the low-grade mill and 6662 lb. of precipitates from the cyanide plant. The total silver treated at the refinery was 812,020 ounces, part of which was at hand at the beginning of the year. The total bullion produced by this plant was 775,253 ounces of bullion and 4070 ounces scrap on hand giving a grand total of 779,323 fine ounces recovered, with residues still to be treated. The total production of silver, including sales of silver, silver on hand and unsettled for at smelter is 705,055 ounces.

The ore reserves are 8000 tons of broken ore ready for extraction, 5000 tons unbroken ore, 5000 tons of ore on the surface ore dumps, averaging about 18 ounces of silver; 300,000 tons of concentrator tailings containing 1,600,000 ounces of silver and 3000 tons of residues from the treatment of high-grade ore containing, besides silver values, cobalt, nickel and arsenic.

Experimental work has been conducted on the residues and tailings with very satisfactory results. Due to these results it has been decided to convert the mechanical concentrator to that of flotation. The flotation plant under construction will have a daily capacity of 600 tons. This tonnage will be distributed as follows: 450 tons of tails and 150 tons mine run ore.

Subsidiary Companies of the Tonopah Mining Company of Nevada.—The *Tonopah Placers Company*, operating at Breckenridge, Col., put two dredges in operation, one in March and one in May, 1915. Their operation was continued until December of the same year, at which time they were shut down on account of cold weather and for necessary repairs. During the past year the indebtedness of \$93,750 contracted by the purchasing of the property was paid off. An initial dividend of 5 per cent was paid in December.

At the *Eden Mining Company*, operating in Nicaragua, C. A., due to litigation, the completion of the

power plant and railroad has been greatly delayed, but at present the work is being rapidly prosecuted. During the past year the machinery for the mill was purchased. The erection of the buildings and installation of the machinery are now being carried on as fast as possible. J. L. Phillips has been elected general superintendent in charge of this property.

Work has been continued on the properties of the *Mizpah Extension Company* and *Tonopah and California Gold Mining Company*, at Tonopah, Nev. A settlement has been made with the Tonopah Extension Mining Company for the ore mined within the boundaries of the property of the Tonopah Mining Company of Nevada.

Chemistry at the Meeting of the American Association for the Advancement of Science

Symposium on the Structure of Matter

The structure of matter was the subject of a very interesting symposium at a joint meeting of the sections on physics and chemistry of the American Association for the Advancement of Science with the American Physical Society, the American Chemical Society, and the American Electrochemical Society, held at Columbia University on Wednesday, Dec. 27, 1916.

The chairman, Prof. Julius Stieglitz, referred in his introductory remarks to the wonderful strides made in recent years in the development of the theory of matter. The old alchemist's dream of transmutation has come true.

Prof. R. A. Millikan of the University of Chicago reviewed the epoch-making researches of J. J. Thomson, Rutherford, Lorentz, De Broglie and others, and emphasized the fact that radiation phenomena have been most instrumental in clearing up our understanding of the structure of matter. Barkla on the basis of his experiments calculated the number of electrons in the atoms of various elements and found this to be approximately equal to one-half the atomic weight. Undoubtedly among the most important contributions to the theory of the structure of the atom are those of Moseley. His work, too, was based on radiation. He found that the vibration frequency of an element increases as the atomic weight increases. Professor Millikan showed a number of new slides which illustrated in striking fashion the shifting of the two characteristic lines of an element toward the violet end of the spectrum upon passing from element of a lower to a higher atomic weight.

Prof. Gilbert N. Lewis of the University of California took exception to some of the theories of the structure of the atom which had been advanced in recent years, and pointed out that it was difficult to apply some of the modern conceptions to many of the organic molecules. He then briefly referred to his theory of polar and nonpolar molecules (*Jour. Amer. Chem. Soc.*, 1916, p. 762). In the polar molecule the electrons move in such a way as to tend to separate the molecule into positive and negative parts, whereas in the nonpolar molecule the electrons do not move far from their original or normal positions. We cannot apply many of our familiar physical laws to the behavior of electrons and atoms; so, for example, Coulomb's law of inverse squares does not hold true at very small or atomic distances. We ought to try to preserve, however, the main body of the electromagnetic theory.

Prof. Robert W. Wood of Johns Hopkins University next read a paper on "molecular resonance and atomic

structure." He described an experiment in which he passed white light through sodium vapor and showed that light was absorbed by the vapor, but partially re-emitted. Sodium vapor will re-emit the D₁ line much more readily than the D₂ line. Iodine vapor has about 120 lines between the D₁ and D₂ lines, and a single one of these can be stimulated. If we excite the iodine vapor with the yellow line of the mercury vapor we get a different grouping of the doublets. Experiments seem to indicate that there is a resonator in the sodium or iodine molecule which does not obey Hook's law.

Wm. D. Harkins, professor of chemistry of the University of Chicago, had chosen for his topic "the evolution of the elements as related to the structure of the nuclei of atoms." With the aid of a number of tables he showed that the atomic weights of the first twenty-seven elements, beginning with helium, are not multiples of the atomic weight of hydrogen by a whole number, as they would be if Prout's original hypothesis in its numerical form were true. However, when these atomic weights are examined critically it is found that they differ from the corresponding whole numbers by a nearly constant percentage difference, and that the deviation is negative in sign, with an average value of -0.77 per cent. This percentage difference has been called the "packing effect," and it represents the decrease of weight and presumably the decrease of mass, which must take place if atoms are complexes built up from H atoms.

The magnitude of the packing effect for helium is 0.77 per cent, so that if a more complex atom is built up of helium groups alone then, in general, nearly all of the packing effect is due to the primary formation of the helium nucleus from four hydrogen nuclei and two negative electrons, and almost no packing effect results from the aggregation of these helium nuclei into more complex atoms.

Professor Harkins described at some length how all the elements might be considered complex helium or helium-hydrogen atoms. He then proceeded to point out that the elements with even multiples of helium or helium and hydrogen are most prevalent.

A second paper by Prof. William D. Harkins of the University of Chicago discussed "the abundance of the elements in relation to the hydrogen-helium structure of the atoms."

According to the theory already presented in a number of papers the atoms of all the 91 elements of our ordinary system heavier than hydrogen are built up as intra-atomic (not chemical) compounds of hydrogen. The first of these 91 elements, helium, is the second in the system, and therefore has the atomic number 2. It has an atomic weight of 4.00, and may be considered to be composed of 4 hydrogen atoms. The element of atomic number 3, lithium, has an atomic weight of about 7. Now it has been found that in general among the elements of low atomic weight, the elements of even atomic number, beginning with helium, seem to be built up from helium atoms, and therefore may be said to have the general formula $n\text{He}'$, where the prime is added to indicate that these elements are intra atomic, not chemical, compounds. The odd numbered elements, beginning with lithium, seem in general to have the formula $n\text{He}' + \text{H}_2$. Thus the elements seem to fall into two series which may be called the *even* and the *odd* series, or the helium and the lithium series, if each series is named for its first member. However, it should be noted that while the formula for the helium series is $n\text{He}'$, that for the lithium series is not $n\text{Li}'$.

If the theory is correct it might be expected that some characteristic of the elements could be found, with respect to which there is a difference from odd to even and from even to odd, or in other words, the elements should show variations in periods of 2 elements each.

In order to have a basis for the comparison of the elements in the study of this problem there has been constructed in space a periodic model of which Fig. 1 is a drawing. In this model the elements are represented by balls strung on a spiral in the order of their atomic numbers,

which have recently been found to be much more characteristic of the elements than their atomic weights. The spiral is so arranged that the balls representing the elements belonging to one group and having the same maximum valence are strung on the same vertical rod. The balls are set at such heights that the vertical distance from the top down represents the atomic weight. This is essential, for otherwise the different kinds of atoms of one element, called by Soddy "isotopes," cannot be represented. Thus in the lower right-hand part of the table, on the lower part of Group 4B, the element lead is represented by 6 isotopes, with the atomic weights listed, as follows: lead from radium (uranio-Pb), 206.1; lead, 207.2; lead from thorium, 208.1; radium D, 210.1; thorium B, 212.1, and radium B, 214.1. Thus the different kinds of lead, which seem identical chemically and give the same spectrum, have atomic weights which differ by as much as 8 units, or by 4 per cent. However, all of these isotopes have the same atomic number, 82, or according to the theory developed by various investigators, they have the same positive nuclear charge.

When arranged in this form of periodic table the elements other than hydrogen and helium are found to arrange themselves in periods as follows:

1. First short period	... Li	— Ne: 8 = 2×2^2 elements	{ Cycle
2. Second short period	... Na	A: 8 = 2×2^2 elements	{ 1 = 4
3. First long period	... K	Kr: 18 = 2×3^2 elements	{ Cycle
4. Second long period	... Rb	Xe: 18 = 2×3^2 elements	{ 2 = 6
5. First very long period	... Cs	Nt: 32 = 2×4^2 elements	{ Cycle
6. Second very long period	Eka	Cs: — (incomplete)	{ 3 = 8

It is thus seen that these periods and cycles make up a numerical system of a remarkably simple form, and it seems evident that this system must express something inherent in the structure of the atoms. However, what it is desired to emphasize here is that nearly all of the physical properties of the elements vary in periods which are either the same or nearly the same as these. The chemical properties also vary in rather long periods, which in the case of the short periods 1 and 2, are identical with those given.

From this it is seen that both the chemical and the phys-

Periodic Table by W.D. Harkins

ical properties of the elements vary in periods which are long in comparison with the change in periods of 2 elements as indicated by the division of the elements into the odd and even series. If now neither the physical nor the chemical properties vary according to these extremely short periods, what, it may be asked, is left which can so vary?

Now it might easily be shown that the hydrogen-helium system of the structure of the elements, which divides them into the odd and even series, is in reality more directly applicable to the structure of the nuclei of the atom than to the atom as a whole. If then the Rutherford theory that the nuclei of atoms are extremely minute, is used as a basis for reasoning, it would be expected that the variation in the structure of the nuclei should not cause variations in the properties of the elements except in so far as they influence the nuclear charge. This nuclear charge has been assumed to be equal to the atomic number, and therefore rises with perfect regularity from odd to even or from even to odd. It seems probable that the number of electrons external to the nucleus is equal to the nuclear charge, and that it is the change in their number and arrangement which causes the physical properties to vary according to the periods listed above. This question has been discussed in a previous paper. (Jour. Am. Chem. Soc., Vol. 38, pp. 186, 203, 281.)

It might be expected, however, that the composition of the nucleus should affect its own stability, which from radioactive evidence means the stability of the atom. From this standpoint it might be reasonable to suppose that the atoms of one of the series, the even or the odd, should be more stable than those of the other. Now unfortunately there is no known method of testing the stability of the lighter atoms, but it might seem, at least at first thought, that the more stable atoms should be the more abundantly formed, and to a certain extent this is undoubtedly true. If then, at the stage of evolution represented by the solar system, or by the earth, it is found that the even numbered elements are more abundant than the odd, as seems to be the case, then it might be assumed that the even numbered elements are on the whole the more stable. However, there is at least one other factor than stability which must be considered in this connection. The formula of the even numbered elements has been shown to be $n\text{He}$, which may be written $n(4\text{H}^+)$. Now, since the formula for the odd numbered elements is $n\text{He} + \text{H}$, or $n(4\text{H}^+) + \text{H}^+$, it is evident that, if the supply of H , needed by the elements was relatively small at the time of their formation, not so much material would go into this system. This would be true whether the H represents three atoms of hydrogen or one atom of some other element. With regard to the latter alternative, it is at least remarkable that the H , occurs 11 times in the system for the first 27 elements, while H_2 and H each occur only once, and it may also be mentioned that Fabry and Buisson⁴ have by interference methods determined the atomic weight of nebium to be 2.7, and this they think indicates that its real atomic weight is 3. Also, Campbell has found that in the nebula N. G. C. Index 418, situated in the southern part of the constellation of Orion, the nebium spectrum is found farther from the interior than that of helium, while the hydrogen spectrum extends out to a much greater distance still. This, he thinks, indicates that the atomic weight of nebium lies between the values for hydrogen (1) and helium (4).

In studying the relative abundance of the elements the ideal method would be to sample one or more solar systems at the desired stage of evolution, and to make a quantitative analysis for all of the 92 elements of the ordinary system. Since this is impossible, even in case of the earth, it might be considered that sufficiently good data could be obtained from the earth's crust, or the lithosphere. However, it seems probable that the meteorites represent more accurately the average composition of material at the stage of evolution corresponding to the earth than does the very limited part of the earth's material to which we have access. At least it might seem proper to assume that the meteorites would not exhibit any special fondness for the even numbered elements in comparison with the odd, or vice versa, any more than the earth or the sun as a whole, at least not unless there is an important difference between these two systems of elements, which is just what it is desired to prove.

A preliminary study of the most recent analyses of meteorites of different classes showed that, either for any one class or for the meteorites as a whole the even numbered or helium system elements are very much more abundant than those of the odd numbered or lithium system. For a more detailed study use was made of the data collected by Farrington,⁴ who suggests that the average composition of meteorites may represent the composition of the earth as a whole.

The results obtained by averaging the analyses of 318 iron and 125 stone meteorites, 443 in all, show that the first seven elements in order of abundance are iron, nickel, silicon, magnesium, sulphur, and calcium; and not only do all of these elements have even atomic numbers, but in addition they make up 98.6 per cent of the material of the meteorites. Of the remaining elements present to a great enough extent to have an appreciable effect upon the percentage values, 7 are odd and 5 are even, but in all only 1.22 per cent or odd numbered, while 98.78 per cent are even.

Of the iron meteorites 99.22 per cent of the material is made up of even numbered elements, and of the stone meteorites, 97.50 per cent. While the results for the earth's lithosphere are not so striking, they still show the same general tendency very strongly; for, of the six most abundant elements, only aluminum is odd numbered, and the elements of even atomic number make up about 86 per cent of the material. The only odd numbered elements other than hydrogen present in the lithosphere in amounts over 0.2 per cent are aluminum, sodium, and potassium.

Table 1 gives the average composition of iron and stone meteorites, arranged according to the periodic system. The numbers before the symbols represent the atomic numbers and the numbers underneath give the percentage of the element. It will be noted that the even numbered elements are in every case more abundant than the adjacent odd numbered elements. The helium group elements form no chemical compounds, and are all gases, so they could probably not remain in large quantities in meteorites. For this reason, and also because the data are not available, the helium or zero group is omitted from the table. The only criticism which could be made of the system of averaging, which is that of including all accurate analyses, is that it that it places undue emphasis upon the iron as compared with the stone meteorites. However, since the two relations shown in Table 1 are true for each class of meteorites separately it is evident that they will be true whatever system of averaging may be chosen.

TABLE I—AVERAGE COMPOSITION OF METEORITES ARRANGED ACCORDING TO THE PERIODIC SYSTEM

Series	Group Odd 1	Group 2 Even	Group 3 Odd	Group 4 Even	Group 5 Odd	Group 6 Even	Group 7 Odd	Group 8		
								Even	Odd	Even
2				6C 0.04%		8O 10.10				
3	11Na 0.17%	12Mg 3.80%	13Al 0.39%	14Si 5.20%	15P 0.14%	16S 0.49%				
4	19K 0.04%	20Ca 0.46		22Ti 0.01		24Cr 0.09	25Mn 0.03	26Fe 72.06	27Co 0.44	28Ni 6.50
	29Cu 0.01									

If attention is now turned to the heavier elements as shown in the model, it is seen that the five unknown elements eka-caesium, eka-manganese 1, eka-manganese 2 (dwi-manganese), eka-iodine, and eka-neodymium, have odd atomic numbers. (There is some doubt as to the discovery of thulium 2.) Not only are the unknown elements odd numbered, but among the radio-active elements, if the most stable isotope of each element is used for the comparison, the odd numbered elements are much less stable than the adjacent elements of even number.

If we consider the rare-earths—the elements which are most similar chemically, while at the same time their atomic numbers change in steps of one—the same result is ob-

TABLE II

Atomic Number	Abundance	Element	Atomic Number	Abundance	Element
55	e	Caesium	63	rr	Europium
56	ccc	Barium	64	r	Gadolinium
57	e	Lanthanum	65	rrr	Terbium
58	cc	Cerium	66	r	Dysprosium
59	r	Praseodymium	67	rrr	Holmium
60	e	Neodymium	68	r	Erbium
61	rrr	Unknown	69	rr	Thulium
62	e	Samarium			

tained. In table 2, which includes, besides the rare-earths a number of elements adjacent to them, the latter *c* indicates common in comparison with other elements in the table, and *r* indicates rare; *cc* represents very common, etc. The comparison is only a rough one, but it is sufficiently accurate for the purpose for it indicates that in every case the even numbered element is more abundant than the adjacent odd numbered element.

The above results may be summarized by the statement that in the evolution of the elements much more material has gone into the even numbered elements than into those which are odd, either because the odd numbered elements are less stable, or because some constituent essential to their formation was not sufficiently abundant, or both.

It is easy to see too that most of the material has been used up in the formation of the lighter elements. Table 2 shows that in the meteorites the most abundant elements are oxygen in series 2, the elements of series 3 except neon, and the members of the first eighth group tried (iron, cobalt, nickel). Clarke has found that just these same elements are the most abundant in the lithosphere, although in the lithosphere potassium and calcium in series 4 are also moderately abundant. If the lithosphere were considered alone it might be considered that the abundance of these elements is due to changes which have taken place in the lithosphere, or to the rising to the surface of the lighter elements, but these objections are not so valid when the meteorites are found to show the same relations.

In the three classes of material, the lithosphere, the stone meteorites, and the iron meteorites, in spite of variations in density from 2.5 to 8, the same two rules are found to hold, that (1) the even numbered elements, and (2) the elements of low atomic number and low atomic weight, are the elements which occur in abundance.

If an artificial line of division is made so as to classify the first 29 elements as of low atomic number and atomic weight, and the remaining 63 elements as of high atomic weight, then the following table, based upon data from analyses listed by Farrington and Clarke may be presented to emphasize the importance of the former class.

TABLE III—PROPORTION IN VARIOUS MATERIALS OF THE ELEMENTS OF LOW ATOMIC NUMBERS

Material	PERCENTAGE OF ELEMENTS WITH ATOMIC NUMBERS	
	1-29	30-92
Meteorites as a whole	99.99	0.01
Stone meteorites	99.98	0.02
Iron meteorites	100.00	0.00
Igneous rocks	99.85	0.15
Shale	99.95	0.05
Sandstone	99.95	0.05
Lithosphere	99.85	0.15

It may be said that, so far as the abundance of the elements goes, the system seems to play out at the end of the first eighth group in the periodic system. It may be of interest to note here, what has been pointed out in former papers, that it is just at this point in the system that the atomic weights cease any longer to be very close to whole numbers, as they are for the lighter weight elements. Also just at this point the exact formula given for the elements ceases to hold well. These facts do not mean, however, that the system fails beyond the iron group of elements; for it is just among the heaviest elements that it received its verification by the actual decomposition of the elements into helium.

Dr. Wm. J. Humphreys of the U. S. Weather Bureau, Washington, reviewed the history of "the relation of magnetism to the structure of the atom." He emphasized that it was the Zeeman effect that had verified the hypothesis of the existence of the electron, and had shown beyond a doubt that electrons are common constituents of all atoms.

Prof. Albert P. Wills of Columbia University in his paper on "the relations of magnetism to molecular structure" pointed out that the magnetic properties of gases had not been investigated thoroughly as yet, and offered a very interesting field for research.

Dr. Irving Langmuir of the General Electric Co., Schenectady, N. Y., read a paper on "the structure of

solids and liquids." He had found that in the case of a tungsten-thoria filament the surface film was 1 atom deep. In general, we can conclude that the substance on the surface decides more or less how the substance as a whole is going to behave. (See Nichols' medal paper, this journal, Vol. 13, p. 244, 1915.)

DISCUSSION

Prof. Wm. Duane of Harvard referred to the remarkable results recently obtained by the use of X-rays, and discussed the determination of wave lengths of X-rays.

In the absence of Prof. J. M. Nelson of Columbia, Dr. K. G. Falk presented his note on "chemical valence and the Grignard reaction." Dr. Falk also presented Prof. L. W. Jones' paper on "a case of chemical isomerism resulting from a difference in distribution of valence electrons."

E. D. Adams pointed out that where our knowledge is still very meager is in regard to the relation between electricity and matter.

Albert C. Crehore discussed the action of one electron upon another. Professor Swan in his usual animated style discoursed on the analysis of a single electron. Prof. A. G. Webster gave a brief summary of our present knowledge of the structure of the atom and was delighted to see the chemists and physicists get together on this most vital subject.

Professor Pupin closed the discussion, emphasizing that he was glad to see the introduction of a rotary electron into our theories. He favored rotation for years. At present we are literally swamped with new theories of the structure of the atom, but sooner or later the various ideas advanced by physicists and chemists from all over the world would be brought together into one co-ordinate whole.

Chemical Session

The chemical session of December 28 was held at the College of the City of New York, Professor Julius Stieglitz being in the chair. Dr. Phoebus A. Levene of the Rockefeller Institute spoke on "the individuality of tissue elements." Within recent years there have been three great achievements in clearing up the relation between chemical structure and the phenomena of life.

First, is the discovery of Dr. Loeb that the permeability of membranes of cells to potassium salts is not a constant, being dependent upon the concentration of the potassium salts. Second, is the discovery that the function of growth is a function of amino-acids having a very definite structure. Third, is the discovery that there is a specificity peculiar to species (hereditary) acid a specificity of mendelian nature (color, etc.).

There are three distinct classes of chemical compounds now known to biologists: (1) The nucleic acids, which occur everywhere, are indispensable to growth, but are not carriers of individuality. (2) The hormones, which are the carriers of Mendelian characteristics. (3) Proteins, the carriers of heredity of species. Our knowledge of these is still very incomplete.

Prof. William McPherson of Ohio State University discussed "asymmetric syntheses and their bearing upon the doctrine of vitalism." He reviewed the work of the early investigators, Wöhler, Pasteur, Wislicenus, Van't Hoff, and others. We still lack a good explanation of the fact that nature's products, such as sugars, are always active, either *d* or *l*, whereas our laboratory products are, as a general rule, inactive. A number of "explanations" have been offered, but the underlying

reason for this difference between the natural and artificial products is still not thoroughly understood.

Dr. Hugh S. Taylor, Princeton University, discussed "the photochemistry of the chlorination processes." This was a theoretical paper, based on observations made by the author in the Bodenstein laboratory at Hannover a few years ago. The general formulas may be written as follows, $(-)$ meaning an electron:

It is necessary that both the chlorine and the hydrogen are exposed to the light rays simultaneously.

Dr. Saul Dushman of the General Electric Co., Schenectady, N. Y., discussed the "application of atomic theories in chemistry." He discussed statistical mechanics, law of probability, Brownian movements, and Maxwell's distribution law.

Dr. Geo. F. Kunz made a brief announcement regarding the chemical preparedness exhibit at the Museum of Natural History.

Professor Stieglitz then asked Dr. Herty to take the chair. Dr. Herty read a telegram just received from Secretary Parsons stating that Professor Stieglitz has been elected president of the American Chemical Society, to succeed Dr. Herty.

Prof. M. T. Bogert of Columbia University discussed "the National Research Council." He gave a brief outline of the aims and purposes of the Council, emphasizing that the Council was not going to direct research, but merely aid. Ten thousand dollars has already been subscribed for the maintenance of a central office, where information of a scientific nature will be obtainable. He concluded with reading the names of the members of the Council.

Dr. C. G. Derick, Buffalo, discussed "equilibrium constants and chemical structure." He demonstrated how the principles of physical chemistry, when applied to organic chemistry, are productive of very important results. As a typical example, he recited his experiment on esters. If the ionization constant for acetoacetic-ethyl ester is K_a , that of acetylacetone K_a , and that of benzoyl acetic ethyl ester K_a , then

$$K_n = \frac{k_1 \times k_2}{k_n}$$

The calculated values for k_n are 0.246 (25°) and 0.234 (40° C.), whereas the values determined by actual measurement are 0.287 and 0.233 respectively.

Dr. F. G. Wiechman discussed the "increased sugar content of the sugar beet after removal from the soil." Due to the action of enzymes, a part of the starch in the beet will be transformed into sugar after the tops have been removed. Wiley and Maxwell (1893) had found an increase of 14.2 per cent. Similar results were obtained with barley in Germany. Wiechman has applied this principle practically. In one of the first tests, 500 lb. of beet cosettes were stored at a temperature of 132 deg. F. The net increase after seven days was 5.31 per cent in the sugar content of the cosettes.

Dr. Edgar Graham discussed "conductivity measurements in oxidation and reduction reactions." In the determination of the acidity of wines, etc., where ordinary indicators fail, Graham has found that conductivity measurements gave very reliable analytical results. Upon the gradual addition of standard alkali solution the conductivity (due principally to the H ion) of the solution dropped very rapidly until the end point

was reached. Further addition of alkali did not alter the conductivity values very much. By plotting the values the end point can readily be located.

M. L. Crossley discussed "valency and valence." Valency is the result of chemical reactions. For example, in the reaction

CH_3 (in CH_3Cl) has a valency of one as a result of the reaction. The paper brought out animated discussion by Messrs. Dushman and Taylor. Dushman objected seriously to the term "dynamic instability" which Crossley had used.

Prof. Gustav Egloff and R. J. Moore of Columbia University, discussed "decomposition of paraffine hydrocarbons." As we proceed from the low fractions C_1 - C_2 , C_3 - C_4 , and C_5 - C_6 to the higher boiling fractions we find that at a certain temperature, e. g. 700 deg. Centigrade the C_{12} - C_{15} fraction is more stable than those immediately preceding or following.

On Thursday evening a session was held at the Museum of Natural History, where Prof. Arthur A. Noyes presented a paper on the fixation of nitrogen. He gave an outline of the successful processes, figures on annual consumption, and data on utilization in arts and industries.

A reception in Philippine Hall closed the chemical meeting.

American Physical Society

Meetings of the American Physical Society, jointly with the A. A. A. S., were held on Tuesday, Thursday and Friday, Dec. 26, 28, 29. Among the forty papers presented, the following will be of particular interest to our readers:

S. Leroy Brown, University of Texas, A new calorimetric resistance thermometer.

Arthur S. King, Mt. Wilson Solar Observatory, California, Experiments with the electric furnace on the anomalous dispersion of metallic vapors.

P. W. Bridgman, Harvard University, The effect of pressure on the resistance of metals and a possible theoretical explanation.

H. L. Dodge, State University of Iowa, The effect of temperature upon the Young's modulus of tungsten wire.

A. W. Hull, Schenectady, N. Y., The internal structure of the atom.

The address of the retiring chairman of Section B (Physics) of the A. A. A. S., Dr. A. Percival Lewis, University of California, dealt with "recent progress in spectrometry," with special reference to its relations to the structure of matter. It is published in full in *Science*, Dec. 29, 1916.

Program of Meeting for Presentation of Perkin Medal

The New York Section of the Society of Chemical Industry will hold its meeting for the award of the Perkin Medal to Dr. Ernst Twitchell on Friday evening, Jan. 19, at the Chemists' Club. The program is as follows:

Introductory Remarks	The Chairman
Presentation of the Perkin Medal and Address	Charles F. Chandler
Acknowledgment by the Recipient	Ernst Twitchell
The Twitchell Process in the Glycerin Trade	A. C. Langmuir
The Twitchell Process in the Soap and Candle Industry	Martin H. Ittner

The Niagara Power Situation

The following joint resolution, authorizing the Secretary of War to issue temporary permits for additional diversions of water from the Niagara River, has been passed by the House of Representatives:

"Resolved by the Senate and House of Representatives of the United States of America in Congress assembled, that the Secretary of War be, and he is hereby authorized to issue permits revocable at will for the diversion of water in the United States from the Niagara River above the falls for the creation of power, to individuals, companies, or corporations which are now actually producing power from the waters of said river, in additional quantities, which, with present diversions, shall in no case exceed the capacity of the generating machinery of the permittee and tenant companies now installed and ready for operation, nor an amount sufficient to enable the permittee to supply the now existing hydroelectric demands of the individuals, companies, or corporations which said permittee and tenant companies are now supplying, but not in excess of the capacity of power-using appliances of said consumers now installed and ready for operation: *Provided*, that in no event shall the total quantity of water diverted in the United States from said river above the Falls for power purposes exceed in the aggregate a daily diversion at the rate of 20,000 cubic feet per second: *And provided further*, that this resolution shall remain in force until the fourth day of March, nineteen hundred and seventeen, and no longer, at the expiration of which time all permits granted hereunder shall terminate, unless sooner revoked; and nothing herein contained shall be held to confirm, establish, or confer in or upon any such permittee any right in or to the water which he is now diverting or which he may be authorized to divert hereunder."

The words in italics are the amendments the Senate would not agree to (the Senate proposing "the first day of July" instead of "the fourth day of March"). This throws the whole proposition into a conference committee of the Senate and House.

* * *

Representative Huddleston has introduced a bill (H. R. 19733) proposing a Niagara Power Commission of three members subject to the general supervision of the Secretary of the Interior. The salary to be \$6,500 for the chairman and \$6,000 for each of the other two members. Its business is to be the production of hydroelectric energy from waters diverted from the Niagara River and its distribution. The power is to be limited to the limit fixed by the treaty between the United States and Great Britain.

"The said Niagara Power Commission shall transmit and distribute, in the United States only, hydroelectric energy to municipalities and consumers convenient to its works and lines, justly and without unreasonable discrimination and as nearly as may be at the cost of delivery plus reasonable charges to cover the expenses of its operations, including the salaries of the commissioners, and plus such further annual charges as will be reasonably sufficient to discharge all of the obligations of said Niagara Power Commission so as to leave same free from debt at the end of a period of fifty years: *Provided*, That no distribution or sales of electric energy shall be made for consumption within the corporate limits of any municipality which may be able, willing and ready to assume the distribution of same therein.

"Said Niagara Power Commission shall use said waters at an efficient head and with reasonable economy, and shall pay into the Treasury of the United States for all hydroelectric energy which may be gen-

erated from said waters at the rate of \$1 per annual horsepower, and no taxes shall be levied upon or collected from it by any State on account of the rights and franchises granted hereby.

"Said Niagara Power Commission may contract with one or more concerns now using said waters for generating hydroelectric energy for supplying said Commission with such energy for not exceeding five years next after the approval of this Act at a reasonable charge, not exceeding \$15 per annual horsepower, such energy when so supplied to be distributed by said Niagara Power Commission as provided by Section 6 of this Act.

"No waters shall be diverted in the United States from said Niagara River above, at, or below the Falls thereof for the purpose of generating hydroelectric energy except by said Niagara Power Commission, and each act of such diversion shall constitute an offense and be punishable by fine of not more than \$5,000: *Provided*, that said Niagara Power Commission may license and authorize such diversion for not more than five years after the passage of this Act for an annual charge or fee of not less than at the rate of \$75 per cubic foot-second.

The Tariff and the Business Commissions

Edward N. Hurley, chairman of the Federal Trade Commission, has resigned from that body, to take effect Feb. 1, with the result that there are now practically two vacancies on the commission which the President must soon fill. Commissioner Rublee has never been confirmed by the Senate, because Senator Gallinger has said Mr. Rublee is "personally obnoxious" to him, Senatorial courtesy allowing the Senator from New Hampshire to prevent the confirmation.

In this connection it is reported in Washington that President Wilson is considering the names of a number of men who would make suitable appointees on both the Federal Trade Commission and the new Tariff Commission, and that he may be expected to announce the names of the latter commissioners shortly. Almost the same type of man is wanted for both commissions.

There is much speculation in Washington concerning the prospective commissioners on these two bodies, and in regard to tariff matters. Secretary McAdoo and the Ways and Means Committee of the House are searching for many additional articles to tax, in the form of tariffs or otherwise, owing to the big deficit in the public funds. The tariff commission when appointed will have much to say on these matters. It was proposed in Washington Wednesday that a tax be placed on business profits in excess of an 8 per cent dividend. This would be a tax of 5 per cent and would yield, it is estimated, about \$200,000,000. Among other items which the Secretary of the Treasury and the Ways and Means Committee of the House are considering are the following: One dollar per horsepower on internal combustion engines, automobiles, \$30,000,000; an output tax on petroleum, copper, aluminium and pig-iron, by the pound, \$81,000,000; 10 per cent on crude rubber, \$15,000,000.

There is a movement on foot in Washington to bring about a method of commissioners serving permanently as chairmen of their bodies, rather than to have the office of chairman rotate as is done in the Interstate Commerce Commission and as was recently done in the Federal Trade Commission. There is a feeling among some public men that the chairman of every Federal commission should be designated by the President. It is claimed that no private corporation could be run successfully without a single and fairly permanent directing head.

The movement to have chemistry represented on the Tariff Commission which we heartily recommended editorially in our issue of Dec. 1, 1916 (page 611), is spreading. Mr. Ellwood Hendrick who had been recommended to President Wilson for a place on the commission by the directors of the American Chemical Society and of the American Electrochemical Society, has since been also endorsed by the Chemists' Club, the American Institute of Chemical Engineers, the Manufacturing Chemists' Association of the United States, the American Pharmaceutical Association, the National Wholesale Druggists' Association, the National Association of Manufacturers of Medicinal Products, and the Technical Association of the Pulp and Paper Industry.

Some Production Statistics for 1916

Gold.—The gold production for 1916 as estimated by the Geological Survey was 4,465,807 fine ounces valued at \$92,316,400, which is a decrease of \$8,719,300 from 1915. California was the leading producer, with over 1,000,000 ounces. Colorado and Alaska were the next in importance, Colorado being but little behind California.

Silver.—There were produced in 1916 about 74,961,000 fine ounces of silver, being a decrease of 2,077,275 fine ounces, according to the Geological Survey. There was, however, an increase in value of \$10,560,000, the average price being \$0.658. Montana was the leading producer, with Nevada, Utah and Idaho running close in the order named.

Copper.—A new record was established in the production of copper. The smelter output, as estimated by the Geological Survey, was 1,928,000,000 lb. and the refinery production 2,311,000,000 lb. The increase in smelter production over 1915 was 540,000,000 lb. and the increase in refinery production was 677,000,000 lb. It is estimated that with additions now being built our refineries can turn out 2,500,000,000 lb. this year if it is required. The American Metal Market Report estimates the supply on hand Jan. 1 at 82,429,666 lb. With exports of 760,000,000 in 1916 this leaves 1,633,429,666 lb. available for home consumption in 1916. Deliveries to consumers are estimated at 1,550,000,000 lb., but how much of this was actually used is not known.

Lead.—A new production was made in lead with 579,600 tons, a gain of 29,500 tons over 1915. There was a decrease of 29,000 tons in the exports of lead of foreign origin and an increase of 21,000 tons in exports of domestic lead. There were 471,200 tons available for home consumption as compared to 426,751 tons in 1915.

Tin.—The production of primary tin direct from ore became a new industry in this country in 1916. The two producers, both of which smelted foreign ore (chiefly Bolivian) turned out over 2000 tons, and the industry should become well established within another year or two. It depends, of course, upon a foreign supply of ore.

Spelter.—The production of spelter from domestic ore in 1916 was 553,000 short tons and from foreign ore 105,000 tons, according to the Geological Survey. Exports were 210,500 tons, and domestic consumption 445,000 tons. The increase in production amounted to 34 per cent, while the exports increased 59 per cent and domestic consumption 22 per cent.

Iron.—Estimates of shipments of iron ore from the mines in 1916 are 75,500,000 gross tons, compared to 55,493,100 tons for 1915. About 49,000,000 tons of

pig iron were produced, compared with 29,916,213 tons in 1915.

Quicksilver.—Quicksilver was produced to the extent of 28,942 flasks of 75 lb. each, valued at \$3,643,800. This was the greatest output since 1905. The figures show an increase of 38 per cent in quantity and 99 per cent in value over 1915.

Chromite.—Two years ago only one small mine in the United States was producing chromic iron ore. This was in Shasta County, Cal. The output in 1914 was less than 1000 long tons. In 1915 it increased to 3281 tons and in 1916 to over 35,000 tons, according to Geological Survey estimates. It comes from California, Oregon, Wyoming and Maryland. The imports were 88,801 long tons during the first ten months.

Petroleum.—Preliminary estimates of the Geological Survey indicate that 293,300,000 barrels of crude petroleum was produced and marketed in 1916. This is 4 per cent greater than the record-breaking year of 1915. It is estimated that 38 per cent came from the Oklahoma-Kansas field and 30 per cent from California.

Coke.—The coke output of the United States broke all records in 1916. More than 35,000,000 tons of beehive coke was manufactured, an increase of over 27 per cent compared with 1915, and 500,000 tons more than the record-breaking total in 1910. By-product coke amounted to 19,200,000 tons, an increase of more than 5,000,000 tons, or 36 per cent, compared with 1915. The total coke production, according to estimates, was 54,300,000 tons, an increase over 1915 of 12,700,000 tons, or 30 per cent.

Coal.—Coal production records were smashed in 1916, when the output was around 597,500,000 tons, compared with 570,000,000 tons, the previous high record established in 1913. The quantity of bituminous coal mined was 509,000,000 tons, an increase compared with 1915 of 66,500,000 tons, or 15 per cent, according to the Geological Survey. The quantity of Pennsylvania anthracite was about 88,312,000 net tons, a decrease of 600,000 tons.

Cement.—Shipments of Portland cement in the United State in 1916 approximated 94,508,000 barrels, an increase over 1915 of more than 7,500,000 barrels, the heaviest shipments in the history of the industry. Production, while it did not keep pace with shipments, reached a total of about 91,194,000 barrels, an increase of more than 5,000,000 barrels over 1915, while stocks fell off more than 3,000,000 barrels.

Lime.—Estimates indicate a total marketed production of 4,150,000 short tons of lime in 1916, or a gain of 15 per cent. This is a new high record. The marketed production of hydrated lime was 710,000 tons, a gain of more than 13 per cent.

The Chemical Industry of Switzerland

Switzerland is one of those countries which, although covered by a vast area of mountainous terrain, is exceptionally poor in all kinds of mineral resources. The main raw materials, coal and iron, are practically lacking, and necessitate their importation from the surrounding nations. Water power is, however, available and is being developed to its full capacity. Hydroelectric power plants have been and are still being built in all sections of the country, where the waters of the swiftly flowing mountain streams justify the investment. The war has to a great extent thrown this small country on its own resources as far as the power question for industrial purposes is concerned, but at the best this power source is insufficient to supply the 107 chemical

plants at present in operation in Switzerland. The bulk of the coal, therefore, at present is obtained from Germany. Previous to the war coal was also imported from France.

Switzerland is blessed with at least two universities, whose chemical engineering departments are ranked with the best in the world. These institutions are the Polytechnikum at Zurich and the University of Zurich, both being independent of one another and financed by the government. From these two main sources come practically all the chemical engineers the country has. The engineers receive their training under men like Treadwell, Lunge, Werner, Lorenz, Vislizenius and others, all prominent figures in the field of chemistry.

The most important chemical industry is undoubtedly the manufacture of synthetic dyes. Besides this branch, Switzerland manufactures pharmaceutical products and chemicals for industrial purposes. There are two types of colors produced in Switzerland, namely, vegetable dyes, chiefly produced from logwood, and coal tar colors. The most important dye industry is undoubtedly the production of synthetic dyes. At least 106 synthetic dyes are at present produced by the various dye factories of the country. These dyes at present are mainly shipped to England and France, but would, under normal conditions, be available for the American market. A list of the colors produced may be found in the Commerce Reports for Nov. 13, 1916. The importance of the Swiss dye industry is best illustrated in the following table, giving the exports since 1896, taken from the mentioned report:

Year	Coal-Tar Colors	Vegetable Dyestuff Extracts	Tanning Extracts	Synthetic Indigo
1896.....	\$2,580,754	\$94,923	\$126,770	
1897.....	3,186,632	117,480	147,627	
1898.....	3,259,539	93,156	135,323	
1899.....	3,172,331	81,860	143,153	
1900.....	2,961,173	69,576	125,347	
1901.....	2,847,389	65,610	123,719	
1902.....	3,081,563	73,871	141,673	
1903.....	3,326,626	76,987	146,778	
1904.....	3,452,436	75,732	138,064	
1905.....	3,862,756	73,068	160,137	
1906.....	4,209,646	72,038	142,803	
1907.....	4,233,533	75,866	139,872	
1908.....	3,793,836	81,538	152,419	
1909.....	4,667,869	94,239	183,640	
1910.....	4,905,002	99,142	223,334	
1911.....	4,920,212	154,044	297,684	\$72,460
1912.....	4,970,474	97,346	315,130	291,334
1913.....	4,794,960	95,987	323,782	754,792
1914.....	5,123,944	84,250	286,252	978,956
1915.....	5,555,738	94,261	289,144	434,525

Next in importance to the dyestuff industry is the manufacture of pharmaceutical preparations. Among the specialties made are protargol, collargol, itrol, a new preparation of a silver protein compound carrying 30 per cent silver and sold under the trade name of solargyl, airol, phytin, throcol, salen, benzalen, vioform, lipogodin, jodostarin and jodogallicin. Besides the above mentioned chemicals, the Swiss factories produce alkaloids, perfumes, cosmetics, and, for industrial purposes, acid potassium tartrate, boric acid, phosphoric acid, sodium, tanning extracts, glycerin, methyl alcohol, coal-tar derivatives, benzylchloride, glue and gelatin.

It is of interest to know that the first chemical factory in Switzerland was built in the year 1764. From that time up to date the number has increased to 107. The products produced in these factories are, under normal conditions, shipped to all parts of the world, while at the present time the export is mainly restricted to China, France, Italy and the United States.

Waste Heat for Steam Generating Purposes.—In our last issue (January 1, 1917) owing to a printer's error, the author's name, Mr. Arthur D. Pratt, was omitted from the concluding part of his article on "The Utilization of Waste Heat for Steam Generating Purposes."

The Human Side of the Development of Chemical Industry*

By G. W. Thompson

Numerous writers and speakers have called frequent attention to the great service which chemistry has rendered to humanity. In every field of industry she has been active, every product of man's labor has felt her magic touch. Modern civilization can be measured most accurately by considering the influence which chemistry has had upon industry and industrial operations. It is unnecessary here to tell what she has done. We are more concerned with the future than with the past, and judging the future by the past, the benefits which chemistry during the coming years will confer upon humanity will be infinitely valuable. On us, her votaries, is imposed the task of laying out the course of her progress, preparing and making the way easy for her and heralding her triumphant march. It is the purpose of this paper to indicate how this may best be done.

It should be perfectly obvious that the purpose of all industry is to satisfy the desires of human beings. This is as true of chemical industry as it is of any other industry. The chemist renders human service. He is a human being himself and his service to human beings makes him a part of a great democratic commonwealth in which every member is a factor in the development of the whole. The chemist is only a fraction in this commonwealth, but the more he is organically a part of it the greater is his power of service. Like everyone else he does not exist by himself alone, but is dependent for his existence upon every other human being that is a part of the social organism.

In the last analysis all of the relations between human beings are mental relations. The instruments of connection between human beings may be material, but the relation itself is spiritual. In so far as the chemist renders service he does so by impressing himself on other people and affecting them either directly through personal contact or indirectly through the products of labor in the fabrication of which he has had a part. Human relationship, therefore, is the end toward which we are perforce all compelled to work. Each man must impress other people and he must in turn be impressed by them. There is no such thing as independence. We are all dependent, and in seeking for what we may nominally call independence we are simply shifting our dependence from one point to another. It is foolish to talk about being independent and it is unwise to seek independence, because it cannot be obtained. Still more important than this, it is best for us that we should not seek independence, but that each one of us should seek to be dependent upon everyone else, thereby conforming to the best conception of human relationships and to the economic law according to which the best service only can be rendered.

What we propose, therefore, is that the chemist should strive against anything that would tend to isolate him and separate him from his fellowmen. What we will try to show is the means by which he can avoid these tendencies, how he may more effectively integrate himself into the social organization.

Perhaps what we have in mind can best be visualized by considering here what has been believed by some to have interfered with the growth of chemistry in this and other countries. For instance, the cry has come from England that technically educated men have not been sought for as the occupants of high official and

*A paper read at the Ninth Annual Meeting of the American Institute of Chemical Engineers, New York City, January 12, 1917.

business positions. It has been claimed that a scientific education did not help towards social or public advancement; that in England a man with a classical education was sought after, not the scientific man. Assuming this to be so, it is perfectly clear that the advancement of the chemist in England has been retarded by a lack of public appreciation of the service which he renders or can render to the nation. What, then, is the chemist in England going to do about it? Apparently he is dissatisfied, which in itself is all right, but being dissatisfied does not alone change inexorable facts. In every chemical problem that confronts the chemist when facts stand in his way he does not get excited about them, but seeks to surmount them by careful study and the devising of ways and means. This should be the attitude of the chemist in England, and by organized publicity—advertising if you will—he should seek to change public opinion so that it will accord to him a higher recognition.

That the English chemist is taking this view is indicated by a recent address by G. G. Henderson before the Chemical Section of the British Association for the Advancement of Science, Newcastle-on-Tyne, 1916. In discussing the synthetic production of nitric acid from the air and the great advantage it would be to England, he laments that England has done nothing in the matter except to appoint a committee to consider possibilities. Then he goes on to say: "This case is only too typical of many others. A number of different causes have contributed to bring about this state of affairs, and the responsibility for it is assigned by some to the government, by others to the chemical manufacturers, and by still others to the professors of chemistry. I think, however, it will be generally admitted that the root of the matter is to be found in the general ignorance of and indifference to the methods and results of scientific work which characterize the people of this country." He adds, however, that he thinks that the English leaders in science have done all that lay in their power to awaken the country to the inevitable and deplorable results of this form of "sleeping sickness," and that he believes that a brighter day is dawning, and that if they rise to the occasion now, chemistry in that country will attain the position of importance which is its due.

Let us take another case. Germany has made great advances in chemistry. Some think that this is due to her system of education, and probably this is partly true. Some think that it is due to the far-sighted wisdom of public men. This, too, is probably partly true, but the real success of chemistry in Germany in my own opinion has been due to its greater popular appreciation. Historians have long since dropped the idea that kings and rulers in general amount to very much in the progress of a nation, and have adopted the broader conception that progress ultimately is in the people of a nation, their developing thoughts, their appreciation of the world that is about them.

The lesson to us in the United States is this—that if we wish chemistry to become a more potent factor in the industrial growth of our country we must take such steps as are necessary to bring about a popular appreciation of its value. Universities will help, government aid will help, but these too depend upon popular appreciation both in their beginning and in their execution; after all, they are mere incidents to fundamental active causes. Create a demand for universities and universities will rise, as it were, over night; create a demand for governmental interest and governmental interest will come quickly and effectively, but demand is born of popular appreciation.

Mr. Elwood Hendrick in an article that appeared not

very long ago in one of our popular journals emphasized this point in urging the popularization of chemistry, and he expressed the thought that chemists would not come into what they believed to be their own until this was done. Mr. Hendrick's suggestion would indicate the advantage of chemists generally advertising their profession, not necessarily, however, in the form of paid advertisements, but in properly written articles for the popular press. The desirability of such a procedure properly carried out is fairly obvious, subject to some limitations, which we will consider further on.

As an illustration of what we can accomplish in this direction I would refer to Robert Kennedy Duncan's writings (particularly his "Chemistry of Commerce") as having been exceedingly efficient in popularizing chemical knowledge, and to the fact that Duncan's efforts in this direction probably resulted in the establishment of the Mellon Institute. As another example of a very commendable effort to popularize chemistry, I would refer to the Chemical Expositions, the second of which was held last September in the city of New York. When the first exposition was proposed, many chemists expressed a great deal of doubt as to its wisdom and practicability, but as the time approached for the opening of the exposition its value to chemists became more clearly recognized and it received from them a very generous and hearty support. So successful was the first exposition that immediately a second one was projected. This received even more generous support, and two of our largest chemical societies decided to hold meetings at the same time. The public press has been full of matter descriptive of the exposition itself and the accomplishments of chemistry thereby illustrated, and gave much space to the papers and discussions, presented at the meetings of the two chemical societies. These expositions were distinctly advertising in their character and great expenditures with the expectation of profitable return were made by the exhibitors themselves.

Our National Departments of Agriculture and Commerce have done much in popularizing chemistry. The work of Dr. Wiley started in the Department of Agriculture has extended the knowledge of chemistry in popular fields through the publication of numerous bulletins and leaflets. More recently the Department of Commerce has, through special investigators, been instrumental in increasing the knowledge of the relation of chemistry to industry. Similar work has been done to some extent by the Department of the Interior.

It seems hardly necessary that I should go further in emphasizing positive aspects of this phase of my subject. Let us consider now some of the criticisms that have been offered on work of this kind. The most general criticism is that when an attempt is made to popularize a science such as chemistry many unscientific statements will be made and true representations will often be incorrectly interpreted by the public. This is undoubtedly so. Erroneous ideas have been promulgated in this way, but the chance to err is not confined to popular presentations. We know that many errors have crept into scientific literature, necessitating laborious effort later on for their correction. To err is human, and the danger that error may occur should not act as a preventive of public statements, whether these are made in the scientific or popular press.

Another objection comes from those who hold that the profession of chemistry is of a very exalted character and that the serious chemist will not descend to ordinary popularizing effort. Our own code of ethics would prevent the chemist from advertising in a sensational manner, and requires the professional chemist to publish scientific papers in the technical journals

before they are given to the popular press. It seems to me that our code of ethics is correct in this respect. We do not want to advocate sensationalism and we do want to build up our technical journals, but after the requirements of our code have been complied with there still seems to be a field open to the chemist in which he can with perfect propriety popularize his science.

The advocates of the study of pure chemistry are also apt to look down upon this popularizing scheme. To them popular science is offensive, and it may be that some of them can hardly be expected to sympathize with the views I am here presenting. The student of pure science is, however, almost in a class by himself. The utmost that he does in affecting the world's processes is by furnishing information, studies and generalizations to be applied by the practical chemist in furthering the interests of the entire world. Far be it from me to depreciate the value of the pure scientist. We all draw upon him for help in our practical efforts. It must be admitted, however, that he lies essentially outside of the plan that we are proposing. He indulges more or less in an esoteric culture and his light, though it is not hidden, is reflected to the world at large only by those who can practically direct that light to the illumination of ordinary things. In spite, therefore, of all that may be said against the popularization of chemistry, I am still convinced of the wisdom of such a purpose, because it is only by so doing that even the student of pure chemistry will be given an opportunity to carry on his studies. So firm is my belief in this that I would extend this effort so that it would reach and include the most humble members of society.

In order to present in picture form, as it were, the dependence of the chemist for his success upon the popular appreciation of chemistry, let me present the following sketch: A chemist makes what he believes is a discovery of great financial value. If he has money enough of his own he may be able to make that discovery a source of financial profit, but in so doing he will have to be something in addition to a chemist, for the largest part of his effort will be along lines which are essentially non-chemical, involving the organization of business, the advertising of the product or process, and its sale for use. In proportion as the public is capable of appreciating what he has accomplished, to just that extent will he make a financial success. Suppose, on the other hand, this chemist is not a man of means and wants to interest financial people in his discovery. As things are to-day he will first encounter skepticism, even ridicule, and if finally he is successful in having his discovery appreciated by financial interests, it will be because he has been able to convince them of its human aspects, and it may be that before he is through a great part of the value which he has seen in his discovery will have been absorbed by what the financial interests think is their proper return. The ordinary business man of to-day very naturally thinks that his business ability is more valuable than the technical ability of the chemist. He wants the lion's share. There is no use in closing our eyes to this fact. Many a poor inventor or discoverer has been so discouraged in his early efforts for recognition that he has been almost ready to drop his entire proposition. He says the blame lies on an unappreciating public, and this is true, but if it is true, how incumbent it is upon the chemist to make the public appreciative. He can do this only by studying the public, finding wherein the public should be educated, and recognizing all its limitations, work with wisdom toward the accomplishment of his purpose.

(To be concluded.)

New York Meeting of American Institute of Chemical Engineers

The winter meeting of the American Institute of Chemical Engineers was opened on Wednesday, Jan. 10, in Rumford Hall, Chemists' Club, New York City, with a business meeting at 10 a. m. In the absence of the president, Dr. Rosengarten of Philadelphia, Vice-President GUSTAV W. THOMPSON, chief chemist of the National Lead Company, presided. And rightly so, for when the committee for canvassing the letter ballots for the annual election of officers (Mr. A. E. Marshall, chairman) presented its report in the evening session, Dr. G. W. Thompson was declared the new president of the Institute by unanimous vote.

The business session in the morning was devoted to the presentation of a long series of reports by the chairmen of the standing committees or in their absence by Secretary Olsen. The monotony of the presentations of committee reports was relieved by a liberal sprinkling of discussions on various angles of professional ethics. Though the Committee on Ethics had not any report of its own, there was more talk—and interesting talk—on ethics during the morning session than we have listened to for a long time.

After the close of the business meeting three papers were presented.

First, an address by the retiring president, Dr. GEORGE D. ROSENGARTEN on chemical preparedness was read by Dr. Olsen in the author's absence. It discussed the peculiar conditions of industrial unpreparedness in which this country was found after the start of the European war.

The paper was referred to the Committee on Public Relations after some discussion in which Messrs. Andrews, McKenna and Withrow participated.

Mr. H. D. MILES, president of the Buffalo Foundry & Machine Company, followed with an interesting review of recent developments in chemical engineering equipment by his company. The Buffalo Foundry & Machine Company was founded sixteen years ago on what was then a radically new basis, namely as a modern foundry on a scientific laboratory-controlled basis. Chemical castings soon became its principal products and the company soon succeeded in turning out caustic pots which had a longer life than European-made pots. Attention was then turned to the manufacture of chemical retorts, acid eggs and acid kettles, as well as vacuum dryers, pumps, and condensers.

Mr. Miles described in some detail the principles of his company's vacuum drum dryer. One of its most extensive uses has been the production of powdered chestnut and hemlock extracts, another the recovery of dry sulphite waste from the waste liquors of paper mills.

When the European war broke out, there was a sudden and large demand for chemical equipment and the Buffalo Foundry & Machine Company entered into the manufacture of equipment for various chemical industries new to this country. Mr. Miles described improvements in machinery for synthetic phenol and the use of the atmospheric drum dryer and sketched advances made in the design of a reducer for the manufacture of aniline oil and of apparatus for the distillation of beta naphthol, the construction of antoclaves for the production of dimethylaniline, the design of new denitrating apparatus for the distillation of nitric acid from a mixture of nitric, sulphuric and water. Mr. Miles finally referred to the manufacture of acid-resisting castings and mentioned the erection of a large research laboratory as the latest undertaking of his company.

A paper by Professor HERBERT T. KALMUS and K. B. BLAKE was then read by title, as printed advance copies of this paper were available. (Several of the papers were printed in advance—a novelty with this Institute and a highly commendable one.) The paper gave the results of a series of investigations extending over a period of several years of the effects on the corrosive properties produced by the addition of various amounts of cobalt, nickel, or copper to a very pure commercial iron. The investigations were made at Queens College, Kingston, Ontario. The results show in general that cobalt, nickel and copper increase the resistance to corrosion. The authors consider the phenomena of corrosion more complex than has been generally stated by the electrolytic theory.

From the authors' summary of results we quote the following:

The corrosion, or loss of weight in grams per square centimeter of original surface per hour, is the function of the length of exposure, being less for the longer exposures. This is true because of the property of these alloys to form a self-protecting layer or coating.

The alloys formed by the addition of small percentages of copper, nickel and cobalt (from 0.25 per cent to 3.0 per cent) to pure iron, are more resistant to atmospheric corrosion than the pure iron, from which the alloys were prepared.

Considering the data for alloys formed by adding various amounts of cobalt (from 0.25 per cent to 3.0 per cent) to pure iron, with very little, if any, carbon content, it is apparent that the corrosion is not a simple function of the percentage of cobalt content. In general, the corrosion of the alloys formed by the addition of 3 per cent of cobalt to pure iron is about 75 per cent as great as that of the alloys formed by the addition of 0.5 per cent of cobalt.

Alloys formed by the addition of 0.25 per cent to 3.0 per cent cobalt to pure iron, with very little, if any, carbon content, are corroded in the atmosphere to an extent varying between 50 per cent and 75 per cent of that of the pure iron from which the alloys were prepared.

These two last conclusions are approximately true for the corresponding nickel alloys as for the cobalt alloys. There seems to be very little choice between the use of nickel and cobalt to form alloys with pure iron containing between 0.25 per cent and 3.0 per cent of the added metal for the prevention of corrosion.

As corrosion progresses, all of the alloys prepared form self-protective coatings of oxides. It is noticeable throughout that the oxides formed by the cobalt are darker, denser, and more tenacious than those formed by the other alloys.

The effect of preventing corrosion of the protective coating just mentioned does not seem to have worked greatly to the advantage of cobalt alloys, in spite of its more satisfactory appearance, in the length of time that the above experiments were allowed to run.

In order to finally conclude the possible ultimate advantages of the cobalt alloy protective coating, as compared with the other sheets, all of the alloys should be allowed to corrode to destruction. The results of such tests, as are being made by the authors, will be published later.

The addition of copper to pure iron to an extent between 0.25 per cent and 0.75 per cent seems to be conducive to reducing the corrosion of the iron under atmospheric conditions. It is difficult to say whether or not the addition of copper in these amounts has a greater or lesser effect than the corresponding amounts of nickel or cobalt. Additional experiments will be required to determine these facts, but there can be but

little doubt that the addition of copper, as above reported, diminishes the corrosion of the pure iron.

The amount of corrosion varies with the percentage of carbon in the alloy, as would be expected.

The paper was discussed in the evening session at great length by Dr. A. S. Cushman of Washington, who after giving a sketch of the history of American ingot iron considered that the authors' tests were inconclusive. He insisted that no conclusions can fairly be drawn from tests with such small samples. Only exposure tests with large full-size sheets give fair results. He has himself such tests going on. The use of nickel and cobalt he considered prohibitive on account of the price. He does not think that the authors' conclusion as to the effect of copper is justified. He considers standardization of quality and material (American ingot iron) to be all important.

Professor JOHN F. BUCHER, of Brown University, Providence, R. I., followed with a paper on the fixation of atmospheric nitrogen. Professor Bucher spoke extemporaneously for over two hours in a most interesting manner. As this was the first public statement of his researches (outside of several patents which were abstracted in our Vol. XII, p. 725, and Vol. XIV, p. 543) he was listened to with great attention. Two points stand out strongly. First, Professor Bucher fixes the nitrogen in form of cyanide. Second, his process does not require a large amount of power and therefore does not presuppose the availability of cheap waterpowers. It can be carried out at any place where sodium carbonate, iron and carbon are available and can be easily carried on in an emergency.

Professor Bucher reviewed former attempts to fix nitrogen as cyanide, all of which were failures, but pointed out that as early as 1837 iron was claimed to be favorable. Professor Bucher indeed found that finely divided iron as a catalytic agent is necessary. His first experiments were made in a tube furnace with the reaction

There is some reaction, but very little. But as soon as finely divided iron is added to the graphite, the reaction became instantaneous:

This is a fine method for getting argon for lecture experiments. The reaction is interesting in another way. If not enough carbon is provided in the mixture, the sodium vapor will absorb carbon from the iron and decarbonize it.

In the present process of the author's sodium carbonate is used instead of sodium. The reaction is

It is an endothermic reaction. The nitrogen need not be pure by any means. Producer gas works as well as nitrogen, neither better nor worse. Finely divided hematite is as good a catalyzer as finely divided iron and much cheaper. The mixture is briquetted simply with water, without any tar or pitch admixtures.

The author then turned to a sketch of the engineering development of the process. Very simple apparatus is required. A vertical tube furnace heated electrically was described (see our Vol. XIV, p. 543). Professor Bucher touched in his further remarks on a great many other researches into which he was led by the development of this process.

After the close of the session there was an enjoyable smoker tendered by the Chemists' Club.

A fuller report of the papers as well as a report of the proceedings at the Friday sessions must be reserved for our next issue.

An Investigation of the Brittleness Produced in Steel Springs by Electroplating

By M. DeKay Thompson and C. N. Richardson

The fact was called to our attention several years ago by Dr. W. H. Whitney that small steel springs become brittle when plated in copper cyanide baths. The object of the following work was to find the cause of this deterioration and under what conditions it does and does not occur.

The steel wire used in these experiments were several sizes of Edgar T. Ward & Sons' "black tempered spring wire" and piano wire.

The first experiments were to determine whether steel springs are injured by plating in a nickel bath containing no cyanide. The bath had the following composition: Nickel ammonium sulfate, $\text{NiSO}_4(\text{NH}_4)_2\text{SO}_4\cdot\text{H}_2\text{O}$, 70 grams; ammonium sulfate $(\text{NH}_4)_2\text{SO}_4$, 10 grams; water, 1 liter.

The pickling solution was 150 cubic centimeters of concentrated sulfuric acid in 750 of water. Short springs were made of black tempered spring wire of the following diameters in millimeters: 1.05, 1.33, 1.65. They were plated at room temperature from one to two hours with a current of from 0.2 to 0.35 amperes. Piano wire of diameters in millimeters 0.28 and 0.33 were plated until their diameters were increased to 0.45 and 0.50 millimeters respectively. The springs were apparently unaffected in any way.

A copper cyanide bath was then made up as follows: Cuprous cyanide, 35 grams; sodium cyanide, 1140 grams; water, 750 cubic centimeters.

A piano wire of 0.46 millimeter diameter was then made into a spring and was plated in this solution with 0.45 ampere. The spring was under a slight tension during the plating and broke at the end of twenty-two minutes. No copper was deposited, the current density being too low. A spring made from black tempered spring wire 1.05 millimeters in diameter was plated with 6.15 amperes and a good deposit of copper was produced. After twenty minutes the spring was removed and was easily broken by stretching.

Larger sizes of the steel and wire of other metals were not affected by plating in this solution, as shown by the following data:

Material	Diameter	Duration of Plating Minutes	Amperes
Steel	1.57	25	10
Steel	2.02	25	10
Steel	2.54	25	15
Brass	0.53	21	10
Brass	1.03	30	10
Phosphor-Bronze	0.64	27	10

None of these wires broke.

In the first experiment in cyanide solution only hydrogen and no deposit of copper was produced, and the spring became brittle. As hydrogen is known to make electrolytically deposited iron very brittle, this suggested that the hydrogen liberated might have penetrated the steel and have caused its brittleness. In order to test this steel springs were electrolyzed as cathodes in a 15.5 per cent sodium hydroxide solution as follows:

Diameter in millimeters	Duration minutes	Amperes
0.33	35	1.50
0.46	49	5.00

They were entirely unaffected, showing that hydrogen is not the cause of the trouble.

A solution of sodium cyanide containing originally no copper was next tried. As a copper anode was used to prevent the escape of cyanogen, a small amount of

copper went into solution during the electrolysis. The results with steel wire were as follows:

Diameter in millimeters	Duration minutes	Amperes
0.29	38	1.5
0.46	9	7.0
1.01	60	14.0

Only the wire 0.46 millimeter in diameter broke. The conditions of the experiment did not remain constant on account of the solution of copper at the anode, causing deposition at the cathode.

A platinum anode was then used, and the cyanogen was passed into a solution of sodium hydrate for absorption. The electrolyzing vessel was a wide mouthed Erlenmeyer flask.

Springs made of 0.46-millimeter wire were electrolyzed for ten minutes with 7 amperes, one in sodium cyanide alone and the other in sodium cuprocyanide. Both were brittle, but the one electrolyzed in sodium cyanide was much more so than the one in sodium cuprocyanide.

It was also found that the wire was most brittle nearest the point of support, and that the brittleness decreased with the distance from this point. This must be due to the greater current density near the support where electrical contact is made.

It was found that the same brittleness is produced in straight wire which has not been bent or coiled. No effect is produced by mere contact with the solution. A spring made of 0.46-millimeter wire was suspended under tension for two hours in a sodium cyanide bath with no current passing. It did not become brittle.

These experiments indicate that the cyanide radical in combination with electrolysis is the cause of the brittleness. The fact that the brittleness is more pronounced in the absence of copper is probably due to the protection the steel gets from the layer of copper deposited. This suggested that the brittleness might be due to a kind of case-hardening by the cyanide radical. These experiments were all at less than 100 deg. C., and such an effect at this temperature seemed very improbable. It was, nevertheless, tested by analyzing the wire for carbon before and after it had been made brittle. The chromic acid method was used (Treadwell-Hall, 1914 edition, page 391). The following results were obtained:

Per Cent Carbon Before Electrolysis	After Electrolysis
0.70	0.73
0.78	0.65
Av. 0.74	0.69

As these check within the limits of the accuracy of the analysis, this suggested case-hardening effect does not take place. This wire was 0.46 millimeter in diameter and was electrolyzed at 80 to 85 deg. C. with 3.5 amperes for one hour and fifteen minutes. The electrolyzed wire was brittle.

There seemed nothing left to explain the brittleness except a possible change in the crystalline structure of the steel. This was therefore examined next.¹

In order to get a polished cross-sectional surface, several pieces of wire were clamped between brass strips, with the ends projecting a little beyond the brass. These were then ground down flush with the brass, and the whole surface, brass and steel, was polished with rouge. The surfaces were etched with a 4 per cent solution of nitric acid in alcohol. The structure of the steel before and after electrolysis did not show any differences.

As all wire is drawn cold and has internal strains, it was next decided to see whether the brittleness is

¹We wish to express our thanks to Professor Henry Fay for his kind assistance in this work.

still produced after internal strains have been removed. In order to remove the strains, some steel spring wire 0.40 millimeter in diameter was heated in an electric furnace as follows:

Time	" C.
11.25	740
11.45	760
12.45	500
12.45	356
1	Room temp.

700 deg. C. is the transition-temperature of 0.7 per cent carbon steel. This wire was then electrolyzed for 1.5 hours with 3 amperes at 80-85 deg. C., without producing brittleness. No difference in the structure was found. Electrolysis of wire as cathode therefore does not produce a change in the structure.

Electrolysis of the wire as anode was next tried. A spring of steel wire of 0.46 millimeter diameter was electrolyzed as anode for fifty minutes with 3.5 amperes at 80-85 deg. C. It was not made brittle.

The surface of the brittle springs and the fractures of the brittle wire were then examined with a microscope for a possible explanation. The surface of the wire showed shallow scratches parallel with the axis of the wire, doubtless caused by the die. The crystal structure could also be distinguished. The majority of the fractures of the brittle wire seemed to follow these scratches, but no further connection between brittleness and scratches was found.

As no other possible explanation of brittleness produced by electrolysis could be thought of, these experiments were for the time at least reluctantly discontinued.

SUMMARY

Though the explanation of the brittleness produced in a spring wire when used as a cathode in a hot cyanide solution could not be found, the following results were obtained:

1. Spring steel becomes brittle when used as cathode in a hot cyanide solution, either sodium cuprocyanide or simply sodium cyanide. The effect is more pronounced with the simple salt. Brass and phosphor-bronze are not affected.
2. Brittleness was not produced by the liberation of hydrogen on the steel.
3. The carbon content is not changed by the electrolysis.
4. The crystalline structure is not changed by electrolysis.
5. The brittleness is not produced in annealed wire.
6. The brittleness is produced by use as cathode whether the wire is coiled or not bent in any way.
7. The brittleness is not produced when the wire is used as anode, or when it is suspended in the solution without the passage of electricity.

The Minerals Separation North American Corporation has been organized under the laws of Maryland with 500,000 shares, having no par value, by the Minerals Separation Co., Ltd., of England, to handle the latter's business in North America. The new company will take over all the assets and business of the Minerals Separation American Syndicate which was formed in 1913 and in which Americans have an interest.

Meeting of the Teknik Club at Denver. On Dec. 12, 1916, the Teknik Club held its monthly meeting. Two papers were presented, one by Mr. Proffitt, entitled "The Use of the Polariscope in the Sugar Industry," and a second one by Mr. J. A. Hunter, "The Work of the State Bureau for the Inspection of Oils."

Analysis of Babbitt Metal; Alloys of Tin, Antimony, Lead and Copper

By E. W. Hagmaier

PREPARATION OF THE SAMPLE

Break or saw the ingots squarely across and file after removing the roughness. If care is taken an accurate sample of the cross-section can be taken. A sample may also be taken by sawing through the ingot several times and collecting the sawings. These sawings or filings should be gone over with a magnet to remove any iron which might contaminate the sample.

ANTIMONY

One gram of the filings is dissolved in an Erlenmeyer flask (800 c.c.) with 10 c.c. of water and 25 c.c. of sulphuric acid. When solution is complete and no black shows in the bottom of the flask remove from the hot plate and cool. Now add 100 c.c. of water and 10 c.c. of hydrochloric acid and boil 10 min. to expel sulphurous fumes. Cool, and add 100 c.c. of water and titrate with potassium permanganate.

TIN

Dissolve a half-gram sample in 30 c.c. of hydrochloric acid in an 800-c.c. Erlenmeyer flask, using gentle heat, and if it is impossible to get complete solution add a small amount of potassium chlorate, but add this sparingly in order not to weaken the acid too much. When solution is complete add 150 c.c. of water and 80 c.c. of hydrochloric acid. Place a strip of ingot iron in the flask and cover with an inverted crucible cover and boil for an hour, or until all the tin is reduced. Remove the flask from the plate and cool quickly; when cool remove the strip of ingot iron and titrate at once with 0.1 normal iodine solution.

LEAD

Place a convenient sample in a 250-c.c. beaker and add 5 to 15 grams of tartaric acid. The amount of this acid depends on the amount of tin in the sample, more tin requiring more of the tartaric acid. To this mixture of acid and sample add 15 c.c. of boiling water and 3 c.c. of nitric acid. When solution is complete add 3 c.c. of sulphuric acid and boil until all brown fumes cease to come off and then give about 1 min. more and remove from the plate.

Care must be taken not to boil too long after the fumes cease to come off, as the sulphuric acid will char the tartaric acid. When all fumes are off cool the solution and add 50 c.c. of water and filter off the lead sulphate, washing the precipitate with 2 per cent sulphuric acid solution. Dissolve the sulphate in hot saturated ammonium acetate solution, add 2 c.c. of acetic acid, bring the solution to a boil and add potassium chromate; boil the contents until the lead chromate settles well. Filter on a tared paper, washing well with hot water, dry at 100 deg. C. and weigh and calculate to lead.

COPPER

To determine the amount of copper treat a larger sample in the same manner as that for tin to the point where the lead sulphate is filtered off; when the lead is filtered off and the precipitate is washed so that no copper remains held in the precipitate, then discard the precipitate and add 2 or 3 c.c. of hydrochloric acid to the filtrate and several pieces of copper-free aluminium and place on the back of the plate and the copper will be thrown out of solution.

When all the copper is thrown out filter off, wash several times with hot water and redissolve the copper

in dilute nitric acid, washing the paper free from all traces of copper and determine the copper by titration or by electrolytic deposition.

COPPER TITRATION

Weigh out $\frac{1}{2}$ gram of copper foil and dissolve in 5 c.c. of nitric acid; when all dissolved and all brown fumes are driven off neutralize with sodium carbonate and then make acid with (1-3) acetic acid and cool. To the cold solution add 3 grams of potassium iodide and stir until this is all dissolved. The solution will be a brown with a white precipitate.

Titrate at once with 0.1 normal thiosulphate solution with continual stirring. As the thiosulphate is run in the brown color will fade; when it is pale add 10 c.c. of a starch solution and continue to titrate until the blue color is gone entirely.

PRECAUTIONS

Keep concentrated, have slight excess of acetic acid, have completely cold before adding the iodide, add sufficient iodide, and stir continually during titration.

Buffalo, N. Y.

Vaporization of Metallic Copper in Wirebar Furnaces

By Allison Butts

The question of the vaporization of copper, silver, gold and other metals in refining furnaces is of considerable importance. It has been known for a long time that there is a loss due to this cause—similar to the evaporation of water from an open vessel at ordinary temperatures—but little has been known either of the extent of the loss or of the circumstances attending it. Some recent experiments give us more knowledge on this subject and afford the basis for some interesting theory. The latter is perhaps at present not of much practical value, but this may develop later in the light of more knowledge and experience.

The present consideration of loss by vaporization was first made in connection with refining of electrolytic copper slimes, when some experiments were made to determine the stack loss. It was found that the bulk of the loss was due to fine particles of slimes carried through the scrubber and out of the stack by the draft. However, the material which passed out of the stack during the later stages of the Doré refining process, when air was being blown into the molten bath, while less in amount was richer in gold and silver, and had the appearance of being mixed with condensed fume. This indicated that part of the loss was due to vaporization.

Any theory with regard to loss by vaporization in the silver refinery was complicated by the fact that a number of different furnaces discharged their gases into the same flue system, by the presence of the scrubber, and by the large amount of metals present as impurities, at least one of which, selenium, forms a comparatively volatile compound with silver. But in the case of other experiments made on wirebar furnaces, there was but one source of metallic vapor to consider, namely, a very pure copper bath.

Copper at the temperature of the melting furnace has an appreciable vapor pressure, and as a result a certain amount of copper vapor from the bath will become mixed with the hot gases and be carried with them into the flue. This amount will be a maximum at the "saturation point" for copper vapor, the limit depending on the temperature in the furnace. Let us first calculate this maximum amount, taking the total pressure at 760 mm., from which it will not vary by more than a

few millimeters, and the temperature at 1120 deg. C., a fair average temperature for the refining process.¹

The vapor tension of copper at 1120 deg. C. is about 0.28 mm. The partial pressure of the copper vapor in the furnace is therefore $\frac{0.28}{760} = 0.00037$. This is equivalent to saying that 0.037 per cent of the total volume of furnace gas is copper vapor.

Measurements of the total volume of gas passing through the furnace and up the stack during the running of one complete charge (time about twenty hours, taken from the time when the charge begins to melt to the end of casting) showed an average of 440,000 cu. m. (15,700,000 cu. ft.) at standard conditions, 0 deg. C. and 760 mm.; 0.037 per cent of 440,000 = 163 cu. m., the volume of copper vapor passing out of the furnace. One cubic meter of copper vapor at standard conditions weighs $0.090 \times \frac{63.6}{2} = 2.86$ kg.; $163 \times 2.86 = 466$ kg. (1025 lb.) of copper per charge.

Now compare this maximum possible loss with the actual loss found by experiment. The furnaces tested were 200-ton reverberatories equipped with waste-heat boilers and economizers. The dust which settles out in the waste heat apparatus and connecting flues was removed usually once a month, and the amount of copper thus recovered averaged over a period of ten months 20 kg. (44 lb.) for each charge of cathodes melted. In addition the bricks and mortar on the inside of the boiler setting become impregnated with flue dust and copper and a certain amount of slag is formed. The boiler slag was recovered from time to time and, together with the coating on the brickwork, accounted for an average of 20.5 kg. (45 lb.) of copper for each charge. The stack loss experiments showed an average of 39.1 kg. (86 lb.) of copper lost from the stack in unrecovered flue dust. Thus there is indicated a total of 79.6 kg. (175 lb.) of copper passing out of the furnace into the flue apparatus each charge.

It seems probable that nearly all of this loss is due to vaporization, since a charge of clean cathodes and remelted refined castings obviously offers little chance for other fume losses, and particles of metallic copper would for the most part be too heavy to be carried by the draft. During poling there is considerable splashing with the formation of minute particles of copper, sometimes called "copper rain," and it is probable that some of this is carried into the first boiler chamber. This question is considered further in connection with the form of the copper in the flue dust. If it is assumed for illustration that all of the 79.6 kg. is vaporized, it means that the percentage saturation of the furnace gases with copper vapor is $\frac{79.6}{466} \times 100 = 17.1$ per cent, an entirely reasonable figure.

The stack loss referred to above was determined by the usual experimental baghouse method. The temperature of filtration of the gas was about 150 deg. C. The vapor tension of copper is not known at this low temperature, but a theoretical value can be obtained by extending the vapor tension curve beyond the known limits. In this way it can be shown that the amount of copper vapor uncondensed at 150 deg. C., and therefore passing through the bags, would be a fraction of a gram.

Suppose the gases leave the furnace at 1120 deg. C. and 17 per cent saturated with copper vapor. They cool immediately to a temperature at which they are 100 per cent saturated by the amount of copper vapor pres-

¹For data on metallic vapor tensions and methods of calculation, see Richards' "Metallurgical Calculations," Vol. 3, pp. 588-593.

ent, and the copper accordingly begins to condense. This temperature can readily be found. At 1120 deg. 466 kg. are necessary for saturation, producing a partial pressure of $\frac{0.28}{760}$. The partial pressure of 79.6 kg.

would be $\frac{79.6}{466} \times \frac{0.28}{760} = \frac{0.048}{760}$, and the vapor tension of the copper vapor would therefore be 0.048 mm. Reference to the curve shows that this tension corresponds to a saturation temperature of 1005 deg. C., or 79 deg. below the melting point of copper.

The furnace gases passed first through the waste-heat boiler, then the economizer, and then up the stack. Typical assays of the dust recovered in each of these places are as follows:

	Boiler dust.	Economizer dust.	Stack dust.
Au. Oz. per ton.....	0.03	0.02	0.02
Ag. Oz. per ton.....	3.00	2.20	1.60
Cu. per cent.....	23.51	18.62	15.03
S. per cent.....	9.41	9.00	7.31
Fe. per cent.....	5.55	7.21	4.47
CuO. per cent.....	1.26	1.27	...
Ins. per cent.....	23.37	25.69	...
SiO ₂ per cent.....	...	...	18.33
As. per cent.....	...	...	0.37
Pb. per cent.....	...	...	0.20
Zn. per cent.....	...	...	Tr.

Other constituents were not determined.

Samples of the three kinds of dust were leached with boiling water. It was found that of the copper in the boiler dust about 60 per cent was soluble, in the economizer dust about 85 per cent, and in the stack dust about 90 per cent. These tests, together with the percentages

FIG. 1—VAPOR TENSION OF COPPER AS FUNCTION OF TEMPERATURE

of sulphur, made it apparent that the copper was largely present as copper sulphate. The vaporized copper must accordingly become oxidized and combine with SO₂, either before, during or after condensation. Anhydrous copper sulphate breaks up into CuO and SO₃ at 670 deg. C., so that any copper which condensed above this temperature could not combine with SO₂, at least until after condensation. The cooling below this temperature, of course, takes place very quickly in the boiler chamber. The gases enter the chamber at a temperature of about 950 deg. C., leave it at 400 deg. C., and leave the economizer at 300 deg. C. It will be noted in the above analyses that the boiler dust has the highest percentage of copper and the lowest amount soluble. This may be taken as an indication of the copper condensed above 670 deg., but it is also to be remembered that some unvaporized particles of copper may be borne into the boiler chamber, especially during piling. More information could be obtained on this point by taking samples of dust at different points in the chamber.

CONCLUSIONS

1. 440,000 cu. m. (15,700,000 cu. ft.) of gas (at standard conditions) pass through one of the 200-ton wirebar furnaces during the treatment of one charge after melting begins, and if saturated would contain 466 kg. (1025 lb.) of copper vapor.
2. 79.6 kg. (175 lb.) of copper actually passes from the furnace, probably due mostly to vaporization.
3. Of this, 39.1 kg. (86 lb.) is lost from the stack, 20.0 kg. (44 lb.) is recovered in dust from the waste-heat installation, and 20.5 kg. (45 lb.) is recovered in boiler slag and clobber.
4. The furnace gases at 1120 deg. C. are nearly 17 per cent saturated with copper vapor.
5. The copper vapor begins to condense at 1005 deg. C., which is about 55 deg. above the temperature at the entrance to the waste-heat boiler.
6. The copper is contained in the dusts largely as copper sulphate. The boiler dust averages about 23 per cent copper, the economizer dust 18 per cent, and the stack dust 15 per cent.
7. The copper in the boiler dust is about 60 per cent water soluble, in the economizer dust 85 per cent, and in the stack dust 90 per cent.

It should be borne in mind that figures on metallic vapor tensions are inexact, being for the most part drawn by inference from the known vapor tensions of mercury and supported by isolated data. Most of the figures given in this article are therefore to be regarded only as approximate. In checking the points on the vapor tension curve, the writer was able to make use of a valuable law of vapor tensions which will be published later by Dr. J. W. Richards, whereby the entire vapor tension curve of a substance may be plotted when a single point is known, *e.g.*, the boiling point of the substance. In determining the graph for copper, the normal boiling point of the metal was taken as 2100 deg. C.

Department of Metallurgy, Lehigh University,
South Bethlehem, Pa.

Meeting of the Utah Section of the American Institute of Mining Engineers. On Dec. 16, 1916, the meeting of the Utah section of the institute was held at the Hotel Utah. The meeting was opened by an informal dinner. Then followed the election of officers for the coming year. After the election, J. M. Callow presented a paper, "Notes on Flotation, 1914." The second paper presented was by Erwin Wilke, entitled "The Manufacture and Use of Sulphuric Acid." A splendid musical program and entertainment helped to make the meeting of more than ordinary interest.

The Calculation of Lead Blast Furnace Charges for Students of Metallurgy

By Boyd Dudley, Jr.

Perhaps there is no better way for the student of metallurgy to become familiar with the chemical and metallurgical principles involved in a smelting process than for him to learn something of the calculation of furnace charges to be employed in conducting the operation in question. Authorities may differ on this point, but certain it is that an understanding of methods of charge calculation is an invaluable aid to the student in his critical study of any smelting process, even though it does not provide him with all of the information he should possess. Furthermore, it is the experience of the writer that charge calculation problems may be undertaken in connection with the ordinary lecture-room metallurgical course with excellent results, on account of the natural appeal that they seem to make to most students. It appears that the student recognizes, without the necessity of having it pointed out to him, that in the solution of these problems there is contained much of the essential information that he should have. Consequently, he approaches the subject with a certain degree of enthusiasm that, unfortunately, is sometimes lacking from his attitude toward other problems.

It is thought that an outline of methods for calculating lead blast furnace charges that have proven useful in class-room work will be of interest to students and teachers—perhaps to others—and it is with this idea that the present paper is presented. That there is nothing new or revolutionary in the methods to be described goes without saying. They are old and have seen long service. But they differ somewhat from those outlined in most metallurgical textbooks, and the presentation of them will therefore serve a useful purpose.

In the first place it may be well to state that a charge calculation generally consists of so determining by computation the amounts of various materials that are to be smelted that these will be present in the proportions necessary to produce, when the charge is actually smelted, a slag of the desired composition. Aside from slag composition there are other considerations to be taken into account in most charge calculations. But these are generally subsidiary to the one first mentioned, and for that reason do not have to be enumerated in detail in the definition.

METHODS OF CHARGE CALCULATION

The ordinary methods of charge calculation may be roughly divided into three classes:

1. The slag-forming constituents of each material on the charge are balanced against each other, and the excess of one constituent over the other is determined. Proper combinations of each of the various materials with the others are then made on the basis of these excesses. This is frequently called the available flux method.

2. Algebraic equations involving the amounts and analyses of the various materials and involving all of the conditions of operation are formulated and solved, the amounts of the different materials being thus determined. From the application of this method rigorously precise results may be expected. But the conditions to be observed and taken into account in the blast furnace treatment of lead ores are usually so complex that the solution of a number of simultaneous equations representing them generally proves to be a somewhat troublesome task. At least there are more speedy and equally exact ways of arriving at the desired result.

3. Preliminary estimates or guesses of the amounts of materials to be employed are made. These are en-

tered on the charge sheet, and the weights of the different slag and matte-forming constituents are calculated from the analyses of the materials. It is then determined whether or not these constituents are present in the proportions required to produce the desired slag and to conform to the assumed conditions of operation. If they are not, a second estimate is made and the correctness or incorrectness of the amended charge is determined as before. This process is repeated until the charge is made to balance in a satisfactory manner. This is frequently known as the "cut and try" method of calculation, the name being derived from the nature of the operations employed to effect a solution of the problem.

When employed by one who has had considerable previous experience in the solution of charge calculation problems, the last mentioned method generally proves superior to the two first mentioned in point of speed, and the results can be brought to the desired degree of precision with a minimum of effort. In the hands of the student, however, this method when used alone frequently fails to demonstrate its superiority over the other two. Because the student has not had the necessary previous experience that is needed to develop the ability to judge with some degree of accuracy the amounts of the different materials to be first tried. Hence the first figures that he enters on the charge sheet may be very poorly selected. Then, too, the student is apt to be prejudiced by his previous scientific training against the use of such a method of calculation. It appears to be inexact and unscientific. The result is not secured by a method of strict mathematical analysis, therefore it ought not to be relied upon.

These and other objections arise in the mind of the student and also in the minds of many of his teachers, when the "cut and try" method of charge calculation is proposed. Some of them are just and some are not. That the result is not secured by a process of strict mathematical analysis cannot be denied, but the exactness of the result is quite another matter. The numerical values that are employed in calculations for such quantities as π and $\sqrt{2}$ are not exact, but by employing the necessary number of figures in the decimal they may be brought to such a degree of precision as may be necessary in the calculation being made. So it is with the "cut and try" charge calculation. In fact, when the vagaries of the ordinary furnace in operation are considered, the result can be brought within the necessary limits with very little trouble. As for the unscientific features of the method, they perhaps consist of nothing more serious than the production of the desired result in less time and with less mental and physical effort than it can be secured with the aid of the available flux or algebraic methods, when either of them is used alone.

But if the student is unable to employ the "cut and try" method with marked success on account of his lack of judgment, then why all this argument in favor of it? Because his judgment can be trained or developed, and this without great difficulty. The quantities of various materials that he first enters on his charge sheet need not be wild guesses. By means of available flux calculations he can make reasonably accurate estimates of the amounts of the most important of his materials, and the final adjustment of the charge can then be accomplished by cutting and trying. The amounts to be cut from or added to the preliminary estimates can also be determined according to available flux calculations. Thus he learns to make these estimates by first applying exact available flux computations to his principal materials. As experience is gained and judgment developed the available flux calculations

as a basis of preliminary estimates can be made of a more approximate nature, and the factors judgment and experience are gradually substituted in their place. This is the method or combination of methods that the writer has found very useful in the class-room calculation of lead blast-furnace charges, and it is this that will be illustrated in the following problems.

MATERIALS SMELTED

In burdening the lead furnace the various materials employed may be classed as ores, fluxes, and fuel. There may not in all cases be a sharp line of distinction between ores and fluxes, and since the differences are largely a matter of definition they need not be discussed at length here.

Ores may be of a number of different types, and a single furnace charge may contain a large number of ores and metallurgical products having various characteristics and analyses. Frequently, however, the relative quantities of some of the ores to be smelted will be determined by the amounts or supplies of them that are available rather than by purely technical considerations. In this event, from the composition of the various ores, the relative amounts of which are so predetermined, there may be calculated at once the composition of the composite material that will result from a mixture of them. Thus in many instances even a long charge sheet may be reduced to a comparatively few items—one or two ores or composites, one or two fluxes, and fuel. It may be well to note in this connection that many smelters follow the practice of actually making these mixtures or composites previous to smelting. This is done by spreading the different lots of ore in layers one above the other, thus making ore beds; or by mixing the lots and storing in bins until the time for smelting them arrives.

The fluxes are generally a material that is rich in lime and one that is rich in iron. This is the case when silicious ores are being smelted, because the slags ordinarily produced in lead blast furnace smelting are essentially igneous solutions of silica, ferrous, oxide, and lime, with other constituents in varying but usually smaller amounts. But where ores are being smelted that are rich in lime or iron, then a material rich in silica would be an essential flux. Of the two first mentioned fluxes the former is generally limestone, which may be more or less dolomitic; while the latter may be either a natural iron ore, or in many cases it may be pyrite cinder or other roasted material containing the necessary amount of iron.

The fuel most commonly employed in modern lead smelting is coke. This may be of varying grades depending on the requirements of the individual case, or more often on the supplies available.

BEHAVIOR OF ELEMENTS DURING SMELTING

Before proceeding with the calculation of a charge for any smelting operation it is necessary to make certain assumptions with regard to the behavior of various elements in the charge during the progress of the process. Such assumptions are at best uncertain, and, in the absence of previous experience in smelting the classes of ores under consideration, it is necessary to make them as reasonable as may be and to let the matter rest with that. However, the student should bear in mind that, while he has to make a number of assumptions and solve his problems with these as a base, in a plant where a furnace is to be started many data are generally available that will show the behavior of similar charges on previous occasions. Even such data are not absolutely trustworthy, however, because differences in furnace construction that appear insignifi-

cant will sometimes produce marked differences in operating characteristics; and two furnaces working side by side under apparently the same conditions and on the same charge will frequently produce different results. So the assumptions that have to be made as a preliminary to class-room charge calculations are intended to be reasonable and to supply the student with the data needed in the solution of his problem, without necessarily corresponding to any special phase of practice.

The principal products formed by the lead blast furnace are metallic lead or base bullion; matte consisting mainly of sulphides of copper, iron, and lead; and slag, which is composed principally of silica, ferrous oxide, and lime. In addition to these there may be speise resulting from the combination of arsenic and iron, when there is much of the former element in the charge. There is always the production of some flue dust, which is carried from the furnace by the rising column of gases; and owing to the volatilization of certain compounds of lead and zinc, arsenic, antimony, and other elements from the hotter portions of the furnace there is always formed a quantity of still another product called fume. The lead, matte, and slag are removed from the bottom of the furnace by tapping, while the gas, dust, and fume are drawn from the top of the furnace through the flue.

Unless the materials to be smelted are of such a nature as will give rise to excessive flue dust and volatilization losses during smelting these factors may generally be disregarded in calculating the charge. This statement does not apply, however, to sulphur and arsenic, since considerable quantities of these elements are oxidized in the furnace and escape with the gases, a point which will be more thoroughly discussed in a subsequent paragraph.

There is nearly always present in the lead furnace charge more or less copper, which for purposes of calculation may be considered as passing into the matte. Of course, some of it will enter the bullion and a little will be lost in the slag, and its concentration in the bullion will increase as its concentration in the matte increases. But for preliminary purposes, at least, the copper may be assumed to enter the matte only.

The iron, on the other hand, will pass partly into the matte and partly into the slag. Under normal conditions of operation iron is needed as sulphide as a matte constituent, and as oxide as a slag constituent.

Of other constituents of the charge that are commonly present, lime, silica, and alumina may be assumed to pass entirely into the slag; while zinc is partly volatilized, partly slagged, and in part enters the matte.

SULPHUR

One of the most uncertain factors in the operating conditions of a furnace, and at the same time a very important one, is the behavior of sulphur. A part of this element of the charge will escape from the furnace with the gases in the form of the sulphur oxides and as elemental sulphur; a part will enter the slag; and the remainder may be considered as combining with copper, iron, lead, zinc, and other metals to form the matte. The distribution of sulphur among these products depends upon many conditions, which include the chemical form in which the sulphur exists in the materials being smelted, the physical characteristics of these materials, the dimensions and lines of the furnace, the composition of the slag, and many other conditions that need not be mentioned here. It is thus evident that previous experience in smelting the materials under consideration constitutes the only reliable guide in making estimates as to the relative amounts

of sulphur that will enter the gas, matte, and slag, respectively. Even with such information at hand such estimates will sometimes be considerably in error, as has been pointed out in a preceding paragraph.

In the absence of such experience reasonable assumptions have to be made with regard to the behavior of the sulphur in the furnace. It may be assumed, for instance, that of the sulphur entering the furnace from 20 to 25 per cent will escape with the gases. The conditions within the ordinary lead furnace are of such a reducing character that no greater evolution of sulphur in the furnace gases is to be expected than this. It may be assumed that the slag produced will analyze 1 per cent sulphur, this being an average figure. After the quantities of sulphur called for by the two preceding assumptions have been deducted from that present on the charge, the remainder may be assumed to enter the matte.

MATTE COMPOSITION

The composition of the matte produced by the lead furnace is another factor of considerable uncertainty, depending as it does on the relative amounts of copper, lead, iron, zinc, sulphur, etc., that may be present in the materials charged, and also on the conditions of smelting aside from the composition of the charge. There may be very little copper and zinc in the charge, in which case the matte will consist mainly of iron and lead sulphides. It has already been noted that all of the copper of the charge may be assumed to enter the matte, and that a part of the zinc will also enter this product. A number of analyses of typical lead furnace mattes show limiting values of the most important constituents as follows:

Lead	5 to 15 per cent
Copper	1 to 15 per cent
Iron	30 to 55 per cent
Sulphur	20 to 25 per cent
Zinc	1 to 10 per cent

Of course, mattes are frequently made the constituents of which do not fall within the limits set by the above table, but the figures given will cover the general run of the lead furnace mattes ordinarily produced. It is evident that there is no particular uniformity as to matte composition, and that any assumption made without previous experience as a guide is likely to be incorrect to a greater or less degree. However, as will be seen later, the important point with reference to matte composition in so far as it affects the calculation of the charge is the ratio of iron to sulphur; and this, in the absence of excessive amounts of copper and zinc, is generally about two to one. This relation may be assumed for the ordinary conditions of lead smelting with a reasonable degree of safety. Certainly it will not lead one further astray than other assumptions of like nature.

ARSENIC AND SPEISE

Arsenic is a common constituent of ores that are smelted in the lead blast furnace, and in the main the behavior of this element is similar to that of sulphur. A part of the arsenic that enters the furnace will combine with iron forming arsenides of various compositions, depending on the conditions of smelting. The percentage of the arsenic charged that enters into such combinations is also quite variable and depends on the composition of the slag, the rate of smelting, etc. It is frequently found that the iron and arsenic have combined in proportions corresponding to the formula Fe_2As_3 , containing 65.2 per cent of iron, which yields a ratio of iron to arsenic of almost two to one. In view of the manifest difficulties in the way of predetermining the behavior of arsenic in the furnace charge this relationship between iron and arsenic may as well be

assumed as any other. So that if the arsenic is present in such quantities as to impose the necessity of including it in the calculation of the charge, some such quantity as 60 to 80 per cent of the arsenic charged may be assumed to combine with iron in the ratio of two parts of iron to one of arsenic. The iron arsenide gives rise to another furnace product known as speise, which may or may not be distinguishable from the matte, depending on the relative quantities of matte and arsenide produced. Mattes will dissolve metal arsenides up to certain limits. Hence with a high matte fall and with little arsenic on the charge the speise formed may not make its appearance as such.

SLAG-FORMING CONSTITUENTS

Silica, ferrous oxide, and lime are the principal slag-forming constituents, and it is with the proper adjustment of these that the ordinary charge calculation deals. When the amounts of zinc, alumina, etc., in the materials to be smelted are comparatively low it is customary to assume that the slag to be produced will consist of a total of 90 per cent of the three principal oxides, the other 10 per cent being composed of alumina, zinc, sulphur, lead, and other elements or compounds generally present in the slag to a greater or less degree. When the amounts of these minor slag-forming constituents in the charged materials are very low, it may be well to assume that the three principals will constitute 95 or 96 per cent of the slag. On the other hand, it may in some cases be necessary to assume that the silica, ferrous oxide, and lime will constitute only 85 per cent of the slag, and that the remaining 15 per cent will be composed of the other substances. The assumption that the three principal oxides will constitute a certain percentage of the slag as produced has to be based entirely upon an estimate of the amounts of the minor slag-forming constituents present. This estimate may be, and usually is, somewhat incorrect, and in the slag as it comes from the furnace the three principal oxides are not present in the exact percentages that have been calculated. But in general the desired ratios of these oxides each to the other will be preserved, and this, in the absence of unusual conditions, will yield a satisfactory slag.

Some metallurgists in calculating their charges follow certain rules that take into account the alumina and zinc oxide and include these constituents in the slag analyses. But it would appear that for students such considerations may well be dispensed with, the first efforts, at least, being concentrated on the adjustment of silica, ferrous oxide, and lime, and the other oxides and compounds being regarded as diluents.

SLAG COMPOSITION

The proportions of the three principal slag-forming constituents to be employed in practice are determined by such a variety of technical and commercial considerations that to discuss them in detail falls outside of the scope of the present paper. It may be well, however, to note a few of the more important factors that govern the selection of a slag.

When the prevailing ore supply of the smelter is silicious in character and basic fluxes are scarce and expensive, the use of an acid or silicious slag is indicated. Of course the reverse of this proposition is also true. Likewise, the relative costs of limestone and iron flux may become determining factors in the selection of the slag. Aside from these and other commercial considerations there are a few more technical points that it may be well to mention. It is generally agreed that in smelting materials rich in zinc the lime in the slag must be kept low and the iron correspondingly high. Zinc

oxide and any considerable quantity of magnesia are also quite incompatible. Alumina may be present to the extent of about 10 per cent without complicating matters greatly, unless at the same time the amount of zinc or magnesia is high. Slags rich in iron and poor in silica apparently have a greater tendency to allow the formation of furnace accretions than do those that are higher in silica and with a greater ratio of lime to iron. These and many other factors must be considered in connection with the selection of a slag, and operating experiences bearing on the point might be cited without end. But for the work at hand, which is the calculation of the charge rather than the selection of the slag, it appears sufficient to state that the general intention in choosing a slag for a particular set of conditions is to employ the one that will yield the best commercial results. The student should bear this point well in mind—dollars and cents constitute the ultimate products of the smelter. But even in the plant it is not always possible to select in advance the slag composition that will yield the best results as measured by this standard, and far less is such a selection possible in the class room. It, therefore, again becomes necessary to employ in class-room calculations such assumptions as appear reasonable in view of the data at hand, and to let the matter rest with that.

While it is possible to vary the relative amounts of silica, ferrous oxide, and lime in the slag within comparatively wide limits, in accordance with the above outlined factors, yet it has been demonstrated by experience that there are practical limitations to such variations. The silica in successful lead furnace slags is generally not less than 28 nor more than 40 per cent. The ferrous oxide varies between 28 and 50, and lime between 10 and 30 per cent. The oxygen ratios of such slags are generally not far from unity, but slags of somewhat greater acidity than corresponds to this ratio are more common than those of less. Modern practice with large furnaces has frequently shown that what were formerly thought to be absolute limitations as to slag composition may sometimes be overstepped, the fusibility and fluidity of the slag under the conditions of its production being the ultimate guides as to its fitness. The ideas that precise ratios between lime and ferrous oxide and that a definite ratio of oxygen in the acids to oxygen in the bases had to be preserved in order to secure a good slag, if they were ever held, have now given way. Both theory and practice have contributed to this end. Laboratory studies have shown that liquid slags may be regarded as igneous solutions of their constituent oxides with the possible presence of associated compounds, rather than as fused compounds or solutions of such that might result from the combination of the oxides. At the same time commercial conditions have frequently prompted the trial of slag compositions that differed considerably from those previously employed, and where such trials met with success new possibilities as to slag composition were established.

Without discussing further the relative advantages and disadvantages of different slags, the compositions of a number of typical lead furnace slags are given in Table I. The names by which the slags are designated are derived from the exact or approximate ratios of lime to ferrous oxide, and in each case the three constituents total 90 per cent as specified in the left-hand columns of figures, and 96 per cent in the right.

Note.—The figures representing silica, ferrous oxide, and lime in the left-hand columns total 90 per cent; those in the right-hand columns total 96 per cent.

The above list of slags does not by any means include all of the compositions that have been successfully em-

TABLE I—TYPICAL LEAD SLAGS WITH SILICA, LIME, AND FERROUS OXIDE, TOTALING 90 AND 96 PER CENT

Name	SiO ₂ , Per Cent		FeO, Per Cent		CaO, Per Cent

ployed in lead smelting. No attempt will be made here to include all of the possibilities, nor to discuss in detail the conditions under which each slag may be properly employed. The compositions that are given, however, are representative and will serve the present purpose.

In order to demonstrate the methods of charge calculation that have been found useful in class room work several graded problems will be stated and solved. These will increase somewhat in complexity from the first to the last, and in the solution of them most of the chemical and metallurgical principles involved in blast furnace smelting for lead are brought before the student. It may be added with much truth that until the student is able to solve such problems with a certain degree of speed and accuracy he can hardly be considered as being familiar with these principles.

PROBLEM I.

Materials of compositions shown in the following table are to be charged to the lead blast furnace.

Material	SiO ₂ , Per Cent	Fe, Per Cent	CaO, Per Cent	S, Per Cent
Silicious ore	40.0	10.0	...	4.0
Iron ore	10.0	60.0	...	1.0
Limestone	5.0	5.0	50.0	...
Coke	5.0	1.0	1.0	1.5

Conditions and Assumptions.—It is desired to produce a slag that will contain silica 33 per cent, ferrous oxide 33 per cent, and lime 24 per cent, leaving 10 per cent to be formed by the various minor constituents not specified in the table. The amount of coke to be employed is 14 per cent of the charge. By the word charge is meant the total weight of ores and fluxes exclusive of the coke.

Assume that 20 per cent of the sulphur charged to the furnace will escape with the gases, and that the slag when produced will contain 1 per cent of sulphur. Assume that the remainder of the sulphur will enter the matte and require twice its weight of iron in forming this product.

Required.—Determine the amounts of limestone, iron ore, and coke to be smelted with 1000 lb. of the silicious ore in order to comply with the conditions and assumptions set forth above.

Notes.—It will be seen that in this first problem no account is taken of the amounts of lead and copper in the materials to be smelted. It is presumed that lead is present in the silicious ore in sufficient quantity to warrant smelting that material with the necessary fluxes. But in order to simplify matters in this first problem the lead will be omitted, and attention directed toward the proportioning of the charge in order to produce the desired slag and the assumed matte.

In the table the slag forming constituents of the coke ash are specified as percentages of the coke as a whole. Of course, these constituents are generally determined on samples of the coke ash, but in calculating the charge it is somewhat more convenient to have the analysis stated as shown.

The iron in the materials to be smelted is specified in terms of metallic iron, while the composition of the slag with respect to iron is stated in terms of ferrous

oxide. This is on account of the fact that it is necessary to consider not only that part of the iron in the charged materials which enters the slag, but also to take into account the iron that enters the matte. It will presently be seen that for purposes of calculation it is a little more convenient to have analyses stated in terms of iron rather than ferrous oxide.

Solution.—A good starting point for such a problem as this is to calculate the ratios of the slag constituents each to the other. In this case it will be most convenient to determine the amounts of iron, lime, and sulphur that will accompany a unit weight of silica in the finished slag. Silica is chosen as the standard because an inspection of the analyses shows that silica is the predominating slag constituent in the silicious ore, and it is for the silica of this material that iron will have to be supplied by the iron ore and lime by the limestone. The slag is to consist of silica 33 per cent, ferrous oxide 33 per cent, and lime 24 per cent; there will also be present 1 per cent of sulphur. Therefore, for each unit weight of silica in the slag there will be present other constituents as follows:

$$\text{Fe} = \frac{33\% \text{ FeO} \times 56 \text{ (atomic weight of Fe)}}{33\% \text{ SiO}_2 \times 72 \text{ (molecular weight FeO)}} = \frac{7}{9} = 0.778$$

$$\text{CaO} = \frac{24\% \text{ CaO}}{33\% \text{ SiO}_2} = 0.727$$

$$\text{S} = \frac{1\% \text{ S}}{33\% \text{ SiO}_2} = \frac{1}{33} = 0.0303$$

That is to say, for each pound of silica present in the slag as produced there must be 0.778 lb. of iron, 0.727 lb. of lime, and 0.0303 lb. of sulphur. With the aid of these factors, it will be a simple matter to determine whether or not the charge is properly balanced after the amounts of the different materials have been estimated. The factors will also be of service in making the estimates.

Next, let a charge sheet be drawn up according to the following form.

CHARGE SHEET, PROBLEM 1.

	Material Weight	Silica		Iron		Lime		Sulphur	
		Per Cent	Wt.	Per Cent	Wt.	Per Cent	Wt.	Per Cent	Wt.
a—Silicious ore	1000	46.0	460	10.0	100	...	...	4.0	40.0
b—Iron ore...	435	10.0	43	60.0	259	...	...	1.0	4.9
c—Limestone	710	5.0	36	5.0	36	50.0	355	...	...
d—Coke, 14%...	307	5.0	15	1.0	3	1.0	3	1.5	4.6
e—Totals	...	...	500	...	430	...	358	...	49.5
f—Silicious ore	1000	...	400	...	100	...	...	...	40.0
g—Iron ore...	500	...	50	...	300	...	...	...	5.0
h—Limestone	725	...	36	...	36	...	363	...	...
i—Coke, 14%...	312	...	16	...	3	...	3	...	4.7
j—Totals	...	...	502	...	439	...	366	...	49.7

In line *a* there is entered 1000 lb. of the silicious ore that is to be smelted. The figures representing the analysis of this material are entered in the spaces provided, and the weights of silica, iron, lime, and sulphur contained in 1000 lb. of the ore are calculated and entered in their respective spaces. In lines *b*, *c*, and *d* are entered the analyses of the iron ore, limestone, and coke, respectively. The amounts of the last three materials have not yet been estimated, so these lines of the sheet are not to be completed until the estimates are made.

In order to estimate the approximate amount of iron ore that must be smelted with 1000 lb. of the silicious ore the following procedure may be adopted. The silicious ore contains 40 lb. of sulphur. According to the assumption as to the disposal of this sulphur in the furnace, 20 per cent will escape with the gases, leaving 80 per cent to enter the matte and slag, 40 lb. $\times 0.80 =$

32 lb. At this point it is possible to estimate only that sulphur which will enter the slag to be formed by the silica of the ore itself. Of course, there will be more silica on the charge than the 400 lb. shown in line *a*, but then too there will be more sulphur than this line shows. So, as a preliminary estimate it will be proper to divide the amount of silica in the silicious ore by 33 in order to find the amount of sulphur of that ore which will enter the slag to be produced with that silica. 400 lb. of silica $\div 33 = 12$ lb. of sulphur to the slag. Considering this ore alone, therefore, and balancing its constituents against each other, the amount of its sulphur that will enter the matte is seen to be 32 lb. — 12 lb. = 20 lb. This sulphur will require twice its weight of iron or 40 lb. The iron shown in line *a* amounts to 100 lb., of which 40 lb. will be required by the sulphur of the ore to form matte, thus leaving 100 lb. — 40 lb. = 60 lb. of iron that will enter the slag. According to the previously calculated slag ratios 0.778 lb. of iron must be present with each pound of silica. The 60 lb. of iron will therefore fulfil the iron requirement of 60 lb. $\div 0.778 = 77$ lb. of silica. The amount of silica in the silicious ore is 400 lb., and with 77 lb. of it provided with iron in the necessary ratio, there remains 400 lb. — 77 lb. = 323 lb., the iron for which must come from an external source—the iron ore.

Consider 100 lb. of the iron ore. It contains 10 lb. of silica, which will require for slag forming purposes 10 lb. $\times 0.778 = 8$ lb., approximately, of iron. Hence of the 60 lb. of iron present 8 lb. must be allowed to accompany the silica of this material into the slag. There is also sulphur present, which will require some of the iron for matte. The amount so required, however, will be small and can be disregarded for the present. The iron requirement of the 323 lb. of silica not already provided with iron will be 323 lb. $\times 0.778$, and if this quantity is divided by 60 lb. — 8 lb. = 52 lb. of available iron in the iron ore, and multiplied by 100, the result will be the approximate amount of iron ore required with 1000 lb. of the silicious ore. Thus,

$$\frac{323 \text{ lb.} \times 0.778 \times 100}{52} = 481 \text{ lb.}$$

At this point the natural question for the student to ask is, "Why make such a fuss about making an estimate of the amount of iron ore required, if the result, when it is obtained, is nothing but an approximation, and perhaps a rough one at that?" The answer to this question is that much more time and space are required to write out the estimate and to explain the way in which it is made than are required by the operation itself. In fact, if the reader will go over the estimate again he will see that, with the exception of solving the last expression, the entire operation can be performed mentally and without the necessity of touching pencil to paper, except to jot down occasional figures for reference; and the final relation can be solved by one setting of the slide rule. It is the intention to make all such estimates of such an approximate character that only quick mental calculations, perhaps concluded by a slide rule setting, are required.

In order to demonstrate the simplicity of the operation, the preceding work may be summarized as follows:

Consider the figures of line <i>a</i> :	
Sulphur to matte and slag = 40 lb. $\times 0.80 =$	32 lb.
Sulphur to slag = 400 lb. silica $\div 33 =$	12 lb.
Sulphur to matte =	20 lb.
Iron on the charge from line <i>a</i> =	100 lb.
Iron accompanying 20 lb. sulphur to matte = 2×20 lb. =	40 lb.
Iron for slag =	60 lb.
Silica present in ore =	400 lb.
Silica provided with iron = 60 lb. $\div 0.778 =$	77 lb.
Silica not provided with iron =	323 lb.

Consider the analysis of the iron ore on basis of 100 lb. of this material, line *b*.
 Iron present in 100 lb. of the ore = 60 lb.
 Iron required by 10 lb. silica = 10 lb. $\times$ 0.775 = 8 lb.
 Iron available for slag forming, neglecting sulphur = 52 lb.
 Amount of iron ore required to supply iron for 323 lb. of silica
 $323 \text{ lb.} \times 0.775 \times 100 = 481 \text{ lb.}$
 52

On account of having neglected the sulphur of the iron ore 481 lb. of this material would prove insufficient for the excess silica of 1000 lb. of the silicious ore; 485 lb. would be more nearly the required amount. Furthermore, while an examination of the analysis of the limestone shows that the silica of this material is provided with slightly more iron than the slag ratio calls for, the coke is seen to have a considerable excess of silica over iron. Hence, after the necessary amounts of limestone and coke are provided, the 485 lb. of iron ore will not furnish enough available iron for the silica thus added, it having been calculated for the silicious ore alone. On this account it might be well to make an addition to the 485 lb. of iron ore in order to bring the estimated amount nearer to the actual requirement of the entire charge, and with a little more experience that is what ought to be done. But without the experience the addition might be made as the result of a somewhat wild guess. It is better for the present to enter 485 lb. of iron ore in line *b* and see how things work out.

Having entered this amount of iron ore, and calculated and entered the amounts of silica, iron, lime, and sulphur thus added to the charge, an estimate of the amount of limestone required may be made. This operation is even simpler than the iron ore estimate, because the lime may be assumed to enter the slag completely; none of it need be deducted for the matte. The amount of silica now shown by the charge sheet is 400 lb. in line *a* and 49 lb. in line *b*, making 449 lb. According to the slag ratio, the lime requirement of 449 lb. of silica is 449 lb. $\times$ 0.727. It will be noted at this point that neither line *a* nor line *b* contain any lime, and for this reason the lime for the entire 449 lb. of silica now known to be present has to be supplied by the limestone. Considering the analysis of the limestone shown in line *c*, 100 lb. of this material is seen to contain 5 lb. of silica, which will require 5 lb. $\times$ 0.727 = 4 lb. approximately of lime. The excess of lime over silica in the limestone is therefore seen to be 50 lb. — 4 lb. = 46 lb. in each 100 lb. of the material. The amount of limestone required to supply lime for 449 lb. of silica according to the slag ratio is accordingly

$$\frac{449 \text{ lb.} \times 0.727 \times 100}{46} = 710 \text{ lb.}$$

Again it will be observed that this amount of limestone is not sufficient for the entire charge. It will provide the silica of the silicious ore, of the iron ore, and of the limestone itself with lime in the proper ratio. But it has already been pointed out that the amount of iron ore entered on the charge sheet will be low, and also it may be seen that the lime in the coke is too low to maintain with the silica of that material the proper ratio. Hence, it is to be expected that the ultimate amount of limestone will be more than 710 lb. However, this amount will be entered on the charge sheet in line *c*, and the amounts of silica, iron, and lime will be calculated and entered.

The estimate of the limestone could be reduced to a very small space as was that of the iron ore, but it will be unnecessary to do this. It should be clear that only the solution of the last expression requires anything more than mental arithmetic.

The charge is now composed of silicious ore 1000 lb., iron ore 485 lb., and limestone 710 lb. Lines *a*, *b* and *c*

of the charge sheet have been completed. Now, if the coke is to be 14 per cent of the charge, then the amount of coke will be (1000 + 485 + 710) lb. $\times$ 0.14 = 2195 lb. $\times$ 0.14 = 307 lb. This amount is entered in line *d*, and the amounts of the various constituents that it contributes are computed and entered.

The columns of figures showing the weights of the respective constituents are now added, and the totals are entered in line *e* of the charge sheet. It will be observed that in each case the weights of silica, iron, and lime have been computed only to the nearest pound, while those of sulphur have been carried to 0.1 lb. The reason for this is that the first three substances are present in relatively large amounts as compared with the sulphur, so that computations to the nearest pound in the one case and to the nearest 0.1 lb. in the other yield results of about the same degree of precision.

The charge may now be tested to determine whether or not the various constituents are present in amounts necessary to satisfy the assumptions and conditions specified in the statement of the problem. It is to be expected, as has been previously pointed out, that both the lime and the iron will be found to be present in insufficient quantities. But by balancing the charge the amounts of the deficits of these constituents can be determined, and increases in the iron ore and limestone can be made accordingly. The following outline will illustrate the method of performing this operation.

Considering the totals entered in line *e*:

Sulphur to matte and slag = 49.5 lb. $\times$ 0.80 =	39.6 lb.
Sulphur to slag = 500 lb. $\div$ 33 =	15.1 lb.
Sulphur to matte after deducting gas and slag losses = ..	24.5 lb.
Iron on charge for matte and slag =	430 lb.
Iron to matte with sulphur = 24.5 lb. $\times$ 2 =	49 lb.
Iron for slag =	381 lb.
Iron required by 50 lb. silica = 500 lb. $\times$ 0.775 =	389 lb.
Deficit of iron =	8 lb.
Lime for slag =	358 lb.
Lime required by 500 lb. of silica = 500 lb. $\times$ 0.727 =	364 lb.
Deficit of lime =	6 lb.

It is thus seen that the charge as shown by the first four lines of the charge sheet contains neither enough iron nor lime to produce the desired ratios of these constituents with the silica present, and to provide iron for the sulphur of the charge that will enter the matte.

In order to supply sufficient quantities of the deficient materials the amounts of iron ore and limestone must be increased. But what is the proper amount to add to each? It will be remembered that the iron ore contains approximately 52 lb. of available iron in each 100 lb. Therefore the approximate amount of iron ore to add will be found by the expression:

$$\frac{8 \text{ lb. (deficit of iron)} \times 100}{52} = 15 \text{ lb.}$$

In a similar manner the deficit of 6 lb. of lime is to be supplied by the limestone, which contains 46 per cent of lime in excess of the amount required to supply its own silica in the proper ratio. The amount of limestone to add is therefore

$$\frac{6 \text{ lb. (deficit of lime)} \times 100}{46} = 13 \text{ lb.}$$

It is well to increase this amount to 15 lb. for two reasons. In the first place it is well to keep the amounts of materials charged in terms of figures ending with 0 or 5, this for ease in computation. In the second place the addition of iron ore that is to be made will increase the amount of silica present, which is not provided with the necessary quantity of lime, by 1.5 lb. The addition of 2 lb. of limestone to the 13 lb. estimated will approximately correct this condition.

In making these changes in the charge sheet the first amounts may be erased and the new ones entered in their places. But from this procedure there generally results a more or less begrimed sheet, and also, in the event of a third or fourth trial being necessary, it will be found more convenient to have the results of preceding trials in evidence on the sheet. Consequently, the new amounts are best entered in a new set of lines below the first, the entries being made in their respective columns, of course. In line *f* enter 1000 lb. of the silicious ore and the corresponding amounts of silica, iron, and sulphur. In line *g* enter 485 lb. + increase of 15 lb. = 500 lb. of iron ore, and compute and enter the corresponding amounts of this ore's components. In line *h* enter the 710 lb. of limestone + its increase 15 lb. = 725 lb.; compute and enter the amounts of components of this material. The coke will be increased in proportion to the other increases, the new weight being $(1000 + 500 + 725) \text{ lb.} \times 0.14 = 2225 \text{ lb.} \times 0.14 = 312 \text{ lb.}$ This amount might be cut to 310 lb. for convenience in calculation, but in this case it will be entered as it is, and the weights of components of the coke calculated from the weight 312 lb. See line *i* of the sheet.

Now, in line *j* the new totals of silica, iron, lime, and sulphur are entered, and the correctness or otherwise of the revised charge is determined as before. The outline of this process follows.

Considering the totals of line *j*,

Sulphur to slag and matte = 49.7 lb. $\times 0.80 =$	39.8 lb.
Sulphur to slag = 502 lb. $\div 33 =$	15.2 lb.
Sulphur to matte after deducting slag and gas losses =	14.6 lb.
Iron on charge for matte and slag =	439 lb.
Iron to matte = 14.6 lb. sulphur to matte $\times 2 =$	49 lb.
Iron for slag =	390 lb.
Iron required by 502 lb. silica = 502 lb. $\times 0.778 =$	390 lb.
Lime on charge for slag =	366 lb.
Lime required by 502 lb. silica = 502 lb. $\times 0.727 =$	365 lb.
Excess of lime over that required =	1 lb.

The balance in this case is satisfactory, that of iron being exact to the nearest pound, and that of lime being within 1 lb. The charge may therefore stand as it was last written, silicious ore 1000 lb., iron ore 500 lb., limestone 725 lb., and coke 312 lb.

The problem that has just been solved is a very simple one, purposely made so in order to illustrate the principles involved in its solution by the method adopted. Of course, the available flux calculations could have been carried throughout, and the amounts of iron ore and limestone required by each material of the charge could have been so determined. But such a procedure would have taken considerably more time and effort than did the one adopted, and the result would have differed in no way from the one obtained.

It may appear that the method of solution employed was a rather "long winded" affair, and, in truth, the description of it does occupy a considerable amount of space. This is due, however, not to the actual amount of work involved, but to the elaboration of details that was attempted in order to make each step in the process perfectly clear. Subsequent problems will illustrate this point, because in solving them it will be unnecessary to enter into such detailed statements.

THE MEANING OF SLAG RATIOS

Before proceeding to the next problem it may be well to deal with a point that frequently proves a stumbling block in the way of the student's understanding of the object of the game in which he is engaged. This point is best outlined by several questions that are almost invariably put when this subject is taken up in the classroom. After the silica has been supplied with iron why is it also necessary to provide lime for it? Does

not the iron of the limestone require lime as well as the silica? Why does the silica in the slag have to be provided with a certain quantity of sulphur, what does it do with this sulphur? These and other questions of like nature are sure to arise, and they are apparently evolved from the idea that a definite chemical appetite of the silica for various other things is the point at issue. This appetite of the silica having been satiated with iron to the full extent of the slag ratio, should not then demand a quantity of lime by way of dessert. But it does, and how can that be? Because the so-called chemical appetite of the silica does not enter into the question at all. Simple arithmetical ratios are the factors involved in this calculation. The only chemistry that appeared was the relation between ferrous oxide and iron, and aside from this there is no chemistry whatever in such a charge calculation.

It is desired to produce a slag that will contain silica 33 per cent, ferrous oxide 33 per cent, and lime 24 per cent. At the same time it is assumed that the slag will contain 1 per cent of sulphur. Simply for convenience in calculation a unit weight of silica was selected, and the quantities of iron, lime, and sulphur that would be simultaneously present with this unit of silica in a slag of the above composition were computed. Any of the other components might have been selected as the standard, and the final result would have been precisely the same. It so happens that in the slag under consideration the components bear this relation to each other:

silica : iron : lime : sulphur = 1 : 0.778 : 0.727 : 1/33.

Now, if the iron on the charge is adjusted to the silica in the proper ratio, and if the lime is also adjusted to the silica in its proper ratio, will not the lime be adjusted to the iron in proper ratio? The answer to this question explains why, in figuring the amount of lime in excess of silica in the limestone, it was unnecessary to allow lime for the iron that was also present. Of course, that iron upon entering the slag would have to be accompanied by lime in proper quantity. But this same lime will also serve to establish proper relations with a certain quantity of silica, which in turn will require the presence of a quantity of iron determined by the slag ratio of silica to iron. Similarly, if 1/33 unit of sulphur is present in the slag for each unit of silica, and if lime and iron are present in definite quantities with reference to this unit of silica, then the proper ratios of iron and lime to the sulphur will be maintained. Will they not? In other words, the object sought in the charge calculation is the establishing of definite mutual ratios between the constituents of the slag—simply this and nothing more. Remember, the ratios are not independent, but each is related to the others in a definite manner,

(To be concluded.)

New Steel Mill in Chile.—The high cost of steel since the outbreak of the European war has started a new steel industry in Chile on a small scale. The raw material used is the old iron, formerly exported to Europe. The skilled labor consists of Spaniards, while the Chileans serve as apprentices. Chilean coal is used as fuel. It necessitated the special building of a foundry for the making of the necessary machinery. The machines to be used are of European pattern. The products of the mill are bars, plates, angles, tees, construction steel, carriage parts, nuts, bolts, nails, tires, etc. The steel produced is 20 per cent cheaper than the imported product. The mill is in operation, and, while the plant is still small, it will undoubtedly serve as the foundation for a big industry, as the Chileans are an aggressive and energetic people.

Countercurrent Decantation*

By Luther B. Eames

Mill Superintendent, Hollinger Consolidated Gold Mines, Ltd.

The recovery of dissolved gold from slime pulp in the cyanide process was first accomplished by intermittent decantation. This simple process consists in mixing with the pulp containing the values in solution, a solution of lower gold content, settling the mixture in a tank and decanting the clear supernatant fluid. The thick pulp remaining in the tank is pumped to a second tank together with more barren solution and again settled and decanted. After several repetitions of this operation, values are so far reduced that further washing is not profitable. The gold recovery of this process is high, but the plant required is bulky, labor cost is high and the amount of solution to be precipitated is excessive.

HISTORICAL DATA

As early as 1901, a plant was built in the Black Hills of South Dakota by John Randall, employing the same principles but attempting to make the process continuous by substituting for flat-bottomed tanks, cones which operated continuously, receiving a constant feed and discharging a steady stream of thickened pulp. These cones were operated in series, the thick underflow of the first one forming, with a stream of diluting solution, the feed to the second cone of the series. Barren solution was added to the tank immediately preceding the discharge tank and, after being slightly enriched by the low-grade pulp in this tank, overflowed to form a diluting solution again for the richer feed entering the third tank from the end of the series, and so on back to the richest tank of the series. Clear water was used for the wash in the final tank. This is the principle on which all successful countercurrent decantation plants operate at the present time, but Randall's plant was not successful because of mechanical difficulties in getting a continuous thick discharge from his cone tanks. A similar plant was built in South Africa, although there the washes were not repeatedly used, as in Randall's case, but were precipitated after each contact with the ore. This also was abandoned because of mechanical difficulties and the cost of precipitating the large quantities of solution that had to be used. For a number of years the process was not used, and it was not until the introduction of the Dorr thickener that the minds of metallurgists began to turn again to the continuous decantation principle.

In 1910, two decantation plants were built making use of flow sheets similar to that used by Randall 9 years before, but substituting Dorr thickeners for the cones. One of these was at Mocorito in Sinaloa, Mexico, and was installed under the direction of C. Dupre Smith, while the other was designed by J. V. N. Dorr, assisted by the writer, for the Vulture Mines Co. of Wickenburg, Ariz. While perhaps not perfect at first, both of these pioneer plants were so successful as to encourage fur-

ther installations, few and scattering at first but in considerable numbers during the past three years.

THEORETICAL CONSIDERATIONS

In view of this increasing importance, the following discussion of the principles and characteristics of the process is offered. For the purpose of investigation a simple yet typical flow sheet has been selected. This is shown in Fig. 1.

This flow sheet assumes that crushing is done in solution, the overflow from the tank T_2 being used for the crushing solution. This crushing solution leaves the grinding circuit with the ground pulp and enters T_1 , and that part which does not pass to the agitators with the pulp overflows T_1 and goes to precipitation. After depositing its gold contents, it is used to dilute the underflow of T_2 as it enters T_1 . The overflow of T_1 is also mixed into the feed to T_2 . The overflow of T_1 mixes with the underflow of T_2 to form the feed to T_3 , and so forth, as indicated in the flow sheet. At each succeeding mixture the solution meets a pulp of higher dissolved content than itself and is enriched while the pulp is correspondingly impoverished. The pulp at each step approaches the discharge end of the mill while the solution goes to the feed end—hence countercurrent decantation.

VARIABLES AFFECTING DECANTATION PROCESS

The principal variables that may affect the efficiency of the process are:

1. Grade of ore.
2. Ratio of solution precipitated to ore treated.
3. Thickness at which pulp can be discharged.
4. Cost of chemicals.
5. Rapidity of dissolving, and the place in the circuit where it takes place.
6. Efficiency of precipitation.

FIG. 1—TYPICAL FLOWSHEET OF COUNTER-CURRENT SYSTEMS

FIG. 2—EFFECT OF VARIATIONS IN GRADE OF ORE TREATED

*A paper to be presented at the New York Meeting of the American Institute of Mining Engineers in February, 1917.

Since the decantation process is one involving volumes and dilutions, it is possible to calculate accurately what distribution of values should take place under any given set of conditions. As far as possible, each one of the above variables has been mathematically considered independently of the rest and the results have been plotted.

The effect of variations in the grade of ore is shown in Fig. 2 and scarcely needs comment. In practice, of course, no such increase as is shown in the gold-solution curve would ever be allowed to take place on account of the difficulty of precipitating such high-grade solution and the danger of leakage, but the graph shows conclusively that all solutions increase in value in direct proportion to the increase in the grade of the ore and that the higher-grade solutions increase at a much more rapid rate than the final washes.

The important part played by the ratio of solution precipitated to ore milled is shown in Fig. 3. For the particular grade of ore considered, which in this case was \$10 recoverable per ton, with precipitation to 3 cents, the economic ratio may be roughly determined by inspection of the lowest curve, which represents the value of the solution leaving the last tank of the series with the tailing. It will be noted that the loss in gold increases very fast as the amount of solution precipitated is decreased, while after a certain point the increased recovery due to increasing the volume precipitated is very slight.

The final choice of the exact ratio to be used must be influenced by the cost of precipitation, which is mainly the cost of zinc. To show clearly the effect of precipitation cost on the economic precipitation ratio, Fig. 4 was plotted. I have considered it safe to assume that the cost of increasing the amount precipitated is due to the additional zinc used. The loss in dissolved gold and the cost of the zinc used in precipitation are both

FIG. 3—EFFECT OF VARIATION IN THE RATIO OF SOLUTION PRECIPITATED TO ORE TREATED

FIG. 4—METHOD OF DETERMINING THE PROPER RATIO OF SOLUTION PRECIPITATED TO ORE TREATED

plotted to the same scale in cents per ton of ore. By adding the ordinates of these two curves a third is formed which represents the total loss in gold and zinc. The lowest part of this curve represents the economical range and indicates that for a \$10 ore, under the conditions assumed with zinc at 26 cents, from 200 to 250 tons should be precipitated per 100 tons of ore treated. In dotted lines are shown the corresponding curves for a \$5 ore under similar conditions. In this case the range is from 150 to 200 tons. While there is a considerable range within which practically identical results may be expected, it is apparent that each operator should figure out for his own conditions just what his range is.

The next, and one of the most important variables to be considered, is the thickness, or percentage of solids,

FIG. 5—EFFECT OF VARIATIONS IN THE PERCENTAGE OF MOISTURE IN THE THICKENER UNDERFLOW

to which pulp can be settled. In Fig. 5 the values of the various overflows have been plotted so as to show the effect of variations in the moisture in the underflows. The full-line curves represent the values of the solutions—that is, they are shown as per ton of solution—but in calculating losses per ton of ore, the ratio of the solution to the ore present must be considered. The loss in dissolved gold per ton of dry ore for the last tank has, therefore, been plotted in a separate curve, and it is this curve which should be given the most serious attention in determining the suitability of an ore for decantation. The moisture in the pulp also has a direct bearing on the cyanide loss, which is also shown in Fig. 5. This has been shown in pounds rather than in cents, because solution strength and the price of cyanide both affect its value. Enough is shown, however, to make it plain that there is a very decided limit to the density of the pulp that can be handled economically, and one is forcibly reminded that the cyanide strength should be kept as low as possible. Operators as a rule seem to be inclined to “play the game safe” as regards solution strength, and it is probable that in many cases cyanide could be saved without any considerable loss in gold by using solutions of a lower strength.

In making the calculations upon which the foregoing curves are based, it was assumed that 75 per cent of the gold was dissolved in the grinding department and the remaining 25 per cent in the agitators. This is, of course, an approximation which cannot be accurate, and even with the cleanest ores some gold is dissolved in passing through the tanks following the agitators. This is a condition that has always been met, no matter what the method of recovering the dissolved value. Changing solution during agitation has been practised for years in the treatment of silver ores, and in the treatment of concentrates at Goldfield with a view to reducing this lag of dissolving. I have also found that on Goldfield ore, pulp from the final agitators, reagitated without change or addition of solution, would give up no more gold, while reagitated filter tails from the same ore would show a distinct reduction. The same condition exists in the pulp fed to decantation plants, and there is little doubt that some dissolving takes place even in the last tanks of the series. Some of this value is lost, particularly that freed near the final discharge, but much is recovered that would probably not be won by any other method. The superintendent of one of the decantation plants treating Tonopah ore informed me that his sampling indicated that the additional dissolving taking place in his plant was sufficient to offset his entire dissolved loss and 3 cents per ton additional.

Any considerable dissolving during decantation will be indicated by a difference in the assay value of the solution in the underflow of the tanks as compared with the overflowing solution. In practice there is always more gold per ton in the underflow solution than in the overflow of any given tank, but in the ores of Porcupine district this difference is very small. Other causes may, and no doubt do, tend to produce this difference between the overflow and the underflowing solution. Adsorption is probably the most important and perhaps the least understood of these. In the case of the ores of the Porcupine district this phenomenon is of small importance, as the ore is composed of crystalline schists and quartz and there is little tendency for the ore to flocculate under the influence of the solutions used. The gold and silver ores of the Western States are in many cases in eruptive rocks; these ores usually flocculate in solution, and in doing so seem to entrap a portion of the value in the solution. At any rate there is a much more noticeable difference in the assays of tank

effluents in the treatment of these ores. This has in some cases been blamed on faulty mixing of the products fed to the tank. In most plants riffles and other devices are put in launders to insure thoroughness in mixing, but our experience in Porcupine would indicate that the ordinary launder makes a perfect mixture. Adsorption, then, would seem to be the more important cause of these differences, and should be a profitable field for further investigation.

Proper precipitation is essential in decantation, as it has always been in every other process, and, as shown by Fig. 6, dissolved gold is lost in proportion to the amount of value in the barren solution used. It will be observed, however, that the loss does not increase as fast as the value of the barren solution does.

It will be observed that the value of the solution leaving T_1 increases at nearly the same rate as the barren solution and that all the preceding overflows increase by exactly the same amount as T_1 . The water dilution cuts the final loss down to a slower increase than the barren solution itself.

Mechanical Features

DORR THICKENER

The mechanics of the decantation system is of the simplest, but is worthy of study none the less. The Dorr thickener is universally used for the separation

FIG. 6—EFFECT OF VARIATION IN THE VALUE OF BARREN SOLUTION

and is so well known and so standardized that it need only be mentioned in passing. It has been fully described by Mr. Dorr himself in a paper read before the Institute.¹

The arrangement of the tanks in plan may be largely governed by space available and other local conditions. In elevation it is very convenient to have the last tank the highest and the preceding ones successively lower, so that the overflowing solutions may be transferred by gravity with a minimum of attention. Where such an arrangement is not possible, the tanks may all be placed on the same level using automatically regulated air lifts to transfer the solutions from tank to tank.

DIAPHRAGM PUMPS

As a means of transferring pulp, the diaphragm pump has distanced all competitors. The main reasons for this are that it not only pumps but at the same time measures the volume of pulp transferred. The flow of pulp is not easily obstructed by foreign matter, such as chips, waste and the like, since the openings are full pipe size straight through the pump. The capacity of the pump can be controlled with certainty by means of cone pulleys. The attendant's duties are all on one floor, as it is operated from the overflow level instead of at the bottom of the tank. Operating cost is very low on a properly designed pump.

Air lifts were used for a time, owing to their cheapness and simplicity, but they are hard to regulate and are wasteful of power. The most careful watching will not prevent them from "running away," that is, transferring too fast, consequently thinning the pulp and sending large quantities of rich underflow solution toward the discharge. On the other hand, if they are set too slow the gradual thickening of the discharge slows up the flow and finally stops it.

Spigot discharge to a bucket elevator or centrifugal-pump sump has also been tried, pulp and solution being mixed and elevated together. There are several objections to this arrangement, the principal one being high power and maintenance cost for the pumping or elevating machinery. Both the solution and the pulp must be lifted more than the full height of the tank for each decantation. The small high-velocity stream of pulp passing through a spigot at relatively high pressure is subject to frequent stoppages due to foreign matter, and even when this does not cause a complete plugging it interferes with uniformity in operation. There is also the objection that work is done on two floors, one below and one above or near the top of the tanks.

There has been a certain amount of prejudice against diaphragm pumps due to the fact that some of the earlier pumps were poorly designed for the work they had to do. Faulty valves were responsible for much of this. Poor methods of regulation also had their effect.

The practice in most plants in the Porcupine district now is to use cone pulleys for the regulation of capacity, although some of the operators favor regulation by varying the length of stroke.

The valves should be of the floating type, as any hinge device will catch the wood chips that are present in the best-screened pulp. The chips lodged in the hinge of the valve cause leaks which, though small in amount at first, cause cutting of the seat and consequently permanent leakage. With the floating valve there is no place for chips to lodge and the whole circumference of the seat is washed by pulp at every stroke. This type of valve also has the advantage that the lower valve may be placed directly below the upper one and made

small enough to be lifted out through the upper-valve seat when the upper valve has been removed. No tools are required for the removal of these valves and it is a simple matter to inspect them.

The best results have been obtained when the working surface of both the valve and seat were of high-grade rubber. Belting was used at first, but it was found that minute leaks were almost sure to start, due to the fact that belting is not yielding enough to close over any chip that may lodge on the valve seat, and that a leak once started would ruin both valve and seat in the course of a few days. On the other hand, valves of rubber seating on rubber have operated six months without the slightest decrease in efficiency and with scarcely perceptible wear.

Diaphragm pumps have been operated at speeds varying from 15 to 100, the higher speeds usually in conjunction with a short stroke.

The practice at the Hollinger mill has been to use a low speed and a stroke as long as the diaphragm could safely stand. Measurements taken on the Hollinger pumps equipped with standard No. 4 Gould diaphragm at 3-in. stroke gave results as shown in the following table:

Number of Strokes	Volume per Stroke, Cubic Feet	Specific Gravity	Per Cent Solids
14.5	0.139	1.54	54.5
23.0	0.148	1.48	50.5
Tons Solids Pumped per Day	Per Cent Increase in Speed	Per Cent Increase in Volume per Stroke	Per Cent Increase in Tonnage
76.3			
114.5	58.5	6.5	50

From the above figures, which are typical of numbers of tests made, it may be inferred that the volume pumped is roughly proportional to the speed of the pump but that leakage is slightly greater on the lower speeds.

The low speeds and the placing of the discharge lips high enough above the discharge valve to leave 3 or 4 in. of pulp over the valve at the end of the upstroke have rendered the pumps of the Porcupine district practically free from the splash and dirt that have been one of the chief objections to diaphragm pumps in the past.

Where tanks have a settling capacity of over 125 tons of solids per day, it may be found advisable to use two diaphragms in parallel, making a duplex or even a triplex pump. This arrangement has several advantages; with the lowered speed, strains of the pump are lessened and distributed, and repairs can be made on one unit without complete stoppage of the tank discharge. Diaphragm life appears to be roughly proportioned to the number of diaphragms employed, while a corresponding decrease in the strokes per diaphragm does not result in an increased cost for diaphragms.

As a safeguard against waste and other foreign matter it is advisable to screen the pulp before it goes to the decantation tanks, and where small wood chips are to be expected a fairly fine screen, usually of punched plate, will be of great service in protecting thickeners and pumps.

MEASUREMENTS OF SOLUTION PRECIPITATED

Every cyanide plant has some method of determining the amount of solution precipitated, and in decantation plants having only one series of tanks the entire tonnage of precipitated solution is used at one place. If, however, more than one series of tanks are used it becomes important to split this precipitated solution into parts proportional to the tonnage of ore being washed in each series. This can not be done by regulating the valve at the outlet of the barren line, as trial has shown that under some conditions an increase of as much as

¹The Dorr Hydrometallurgical Apparatus, *Trans.*, vol. 49, pp. 211-237 (1914).

50 per cent can be made in the amount flowing from a pipe line without any visible change in the stream.

This difficulty has been overcome by the use of V-notch weir boxes, one for each series of tanks. In each weir box is a float compartment and a float operating an indicator on a scale which reads in tons per 24 hr. While the weir box, which can be readily made at any mine, is not a recording instrument but gives only an instantaneous rate reading, its use greatly simplifies the problem of proper distribution of barren solution. Water also should be added in proper amounts and uniformly distributed. A smaller weir box has been found convenient for this purpose.

It is usual to determine the specific gravities of various pump discharges about a decantation plant at least once a shift. In a small plant this consumes little time but if there is a large number of measurements to be made the distance to be covered by the operator is considerable, especially if he has to return to a central point for each weighing. In such plants, a spring balance with a dial and revolving hand, that can be carried about the plant, is a good type. I have used a milk scale having an adjustable tare-indicating hand, which makes one complete revolution for 10 lb. I use a narrow-necked can which holds just 10 lb. of water when level full. This makes it possible to add a paper dial which can easily be divided so as to read directly specific gravities. The large sample makes possible accurate readings and enables the operator to determine gravity at the place where the sample is taken.

TRAY THICKENERS

In his paper on the Dorr metallurgical apparatus, Mr. Dorr touched on the future of tray thickeners, and spoke of the possibility of a complete decantation plant being installed in one tank. While this has not been done as yet, a four-step decantation followed by a continuous filter is in operation, the four steps of the decantation being completed in two tanks equipped with single trays. While no figures have been made public the results are said to be creditable.

Another use of the tray in decantation, which is shortly to be tried at the Hollinger mill, is to increase the capacity of existing plant rather than to decrease the number of tanks installed. Since the same grade of solution is handled in both tank and tray there is no danger of any mixing of solutions of different grades. This plan should decrease the cost of buildings, tank foundations and building site in almost direct proportion to the increase in capacity gained, while tank cost, power and labor should all be decreased to a marked degree. The outcome of this experiment should have a direct bearing on the future of the decantation process. It must, however, be borne in mind in this connection that some slimes require time for their final thickening and consequently necessitate a tank of some depth, while other slimes find their capacity limit in the thin-pulp settling rate. For this latter class, as explained by Messrs. Coe and Clevenger in their paper on slime settling,² a shallow tank or tray is sufficient while the former class requires a tank of carefully calculated depth to give the required time for thickening.

The Decantation Plant of the Hollinger Co.

The Hollinger decantation plant consists at present of five rows of 40-ft. tanks, four tanks to a row, forming a plant of five units. The tanks are arranged with a difference in elevation of 2 ft. 6 in. between steps with the final tanks of the series the highest, so that all solutions gravitate through and out of the plant to precipi-

tation. The Barrett specification roof is supported on flat trusses, the lower cords of which pass just above the tank rims. These trusses also serve to support the thickener mechanisms as well as the walks between the tanks.

The diaphragm pumps used were designed by the company's staff, and have been very reliable and economical. They are all three-throw or triplex pumps so that in spite of the large tonnage handled the duty on each diaphragm is light. It is not uncommon for diaphragms to last 300 days while the life of the present type of valves and seats has yet to be determined.

The pumps are used not only for pulp transferral, but also for the final discharge. This makes regulation of the final discharge for moisture much easier, more reliable, keeps the work of the operator all on the upper floor and allows the tailing to be discharged at a considerably greater elevation than would otherwise be the case.

The barren solution and water wash added to each row are measured by separate float-reading weir boxes assuring uniform results from the various units.

LABOR

The plant is operated by one man per shift who oils all machinery, watches and adjusts the pumps and records their performance. The solution man makes titrations and regulates the addition of water solution but has no other duties in the decantation plant. A repair man on day shift makes all repairs and has time for other work.

POWER

The power for each tank including motor and line-shaft losses is under 1 hp., while each three-throw pump consumes about the same amount.

COST

The costs for the twelve weeks from Jan. 23, to April 21, 1916, have been taken as typical of what is done by this plant at its present capacity. During this time 85,854 tons were decanted at a cost of \$599 for supplies, including power, and \$1,194 for labor, or \$0.007 per ton for power and supplies, and \$0.0139 for labor, making a total of \$0.0209 per ton for decantation. Labor is no doubt higher here than it will be in the future, as a greatly increased tonnage is to be treated while supplies and power should remain nearly the same. The cost as it stands is about 40 per cent of the cost of filtering on leaf filters at about the same daily tonnage.

EXTRACTION AND RECOVERY

In the ores of the Porcupine district the recovery by dilution seems to be almost the theoretical maximum. Adsorption does not seem to have any appreciable effect. There is a slight dissolving during decantation which, while it adds to the recovery, makes the soluble loss somewhat greater than it would otherwise be.

The figures quoted below on chemical consumption and recovery refer to only two units of the Hollinger plant. The figures on these units are given because the other units of the mill share their feed with the original Moore filter plant, and likewise their barren solution, while for commercial reasons the two units in question have been given a separate solution system and separate precipitation presses. These two units are therefore the only ones upon which all the figures are available.

In comparing the results quoted, however, it should be borne in mind that the flow sheet has been modified in this plant somewhat because of limitations of space, so that the overflow of T_1 instead of that of T_2 goes to precipitation. The effect of this is to raise the theo-

²Laboratory Method for Determining the Capacities of Slime-Settling Tanks, *Bulletin* No. 111, p. 597 (March, 1916).

retical value of the overflow of the last tank 3 cents at 3 to 1 precipitation.

A statement of results follows:

Period covered, same as that for which costs were given—from Jan. 28, 1916, to April 21, 1916.

Tons of ore treated	38,885
Value per ton of ore	\$3.92
Ratio of ore to solution precipitated	100 to 285
Tons solution precipitated	110,604
Strength of cyanide used	0.9 lb. per ton, or 0.0045 per cent
Cyanide added per ton of ore	0.46 lb.
Difference between pulp feed and pulp discharge for first tank after agitators	25 c.
Average moisture in tails	45 per cent
Average value of barren solution	3.2 c.
Dissolved gold per ton of solution discharged	11.71 c.
Dissolved gold per ton of ore discharged	9.57 c.

It is theoretically possible, taking into consideration the flow sheet, the grade of ore treated, the barren solution used and the thickness of pulp attained, to have reduced the overflow of the last tank to 7.6 cents, leaving a difference of 4.1 cents to be accounted for by continued dissolving adsorption, etc.

Viewed in one way it may be said that actual losses are 54 per cent higher than theoretical, but where one is dealing with samples so easily affected by faulty manipulation and where any error except losses in assaying tends to raise the results, a check to 4 cents does not seem bad. The average loss would have been somewhat less if the occasional high results had been omitted, but this was not done.

From the foregoing, I believe one is warranted in concluding that a reasonably accurate forecast can be made of the results to be expected from a decantation plant and that these results may compare very favorably with the results obtained from filter plants.

In conclusion I would say that I am indebted to P. A. Robbins, managing director of The Hollinger Company, for permission to quote results from the Hollinger plant.

Timmins, Ont., Canada.

The Rubber Situation

By Andrew H. King

In a previous paper I outlined the rubber situation as far as this country is concerned. I endeavored to show that we as a people are almost absolutely dependent upon Great Britain for our supply of crude rubber, the utilization of which material goes hand in hand with civilization. If you wish to see what a rubberless community would be like, look on Germany. Her supply is so low that rubber is only used in cases of absolute necessity. Consider her wooden tired motor trucks, and her celluloid nursing nipples. What did the merchant submarine Deutschland take back with her? Gold? No, mostly rubber. It is exactly such a situation that we as a people must guard against.

The proposition is full of pitfalls, even in peace times. The British will certainly be human enough to make us stand their bills for the great war if they can find a means to do so. It has already been suggested by certain unofficial sources that there should be an export duty on rubber. Straws show which way the wind blows, and while nothing really definite has been done, it is evident that they are looking for a way out.

It will be remembered that a few years ago, when Germany first began to put the screws on the potash exportation, that certain enterprising Americans bought in on the ground floor. The matter is now history, but the fact remains that they got out with a brand new lesson in their hats, namely the wisdom of staying away from a foreign monopoly. Several of our rubber companies may have to learn the same lesson, for it is well known that certain plantations in Sumatra and in the Federated Malay States are controlled, if not owned out-

right, by American capital. Considerable weight is given the old saying that blood is thicker than water. These capitalists place great faith in Englishmen, and while I do not wish to injure that faith, I cannot refrain from pointing out the confiscation of German patents by Great Britain. If she will confiscate intellectual property, what may she do to real property in the event of a slight misunderstanding between our respective countries?

There is quite a similarity between the potash and rubber situations. If given time enough it now appears that we will solve the former. The importance of American control has been effectually demonstrated. We must not allow the German monopoly to crush out this infant industry, for should this calamity occur the foundation of our national existence would be weakened, and ultimately a condition might arise when we would learn again that a chain is no stronger than its weakest link.

Fortunately, the rubber problem is not nearly as serious, nor nearly as difficult of attack as that of potash. We have plenty of methods of approach, plenty of skilled minds to call upon, and only lack the necessary capital and incentive. Only a few years ago we saw such an epidemic of wildcat speculation in rubber, and particularly in synthetic rubber, that the general public has been rendered a little leery of rubber investments. However, better times have dawned, and our bankers have learned that there are certain reliable persons called experts who will advise them well. Consequently we have reason to hope for action.

Let us grant for sake of argument that we need an American rubber industry. Let us also grant that we have the necessary capital to go into the matter. How shall we go about it? What avenues lay before us? Shall we pin our hopes to the Guayule shrub, or to any other cousin shrubs which happen to bear rubber? Shall we establish plantations in the Philippine Islands, or in Hawaii? Or shall we resort to the chemist and plunge on synthetic rubber?

In a previous paper I discussed Guayule. The possibility of its revival is very certain. Ever since 1912 considerable shrub-bearing areas have been idle—practically untouched. When the Mexican trouble is over this will mean a large Guayule harvest. At such time a program of conservation must be adopted or the plant will become extinct.

There are other plants acclimated to temperate zone conditions that are worthy of passing mention.

Our common milkweed, *Asclepias Syriaca*, is a rubber producer. It grows abundantly throughout the United States, and is probably better known than any other weed. Its latex, as reported by Fox (*India Rubber World*, 1914, page 645), is thin, milky, and possesses an acid or neutral reaction, besides the characteristic milkweed odor. It may be coagulated by heat or by alcohol. The coagulum is plastic, and when molded into cakes resembles low-grade rubber. The rubber present is of inferior quality, and on the basis of latex represents a yield of only 2 to 3 per cent. The resin contains asclepiadin, which drug finds application in drosy, etc. The rubber might be improved by Spence's sodium process, but the production of anything like commercial quantities would involve so much asclepiadin as to make this otherwise moderately valuable by-product a liability rather than an asset. A point which has been overlooked heretofore is the fact that this weed produces at seed-time a very beautiful, pure white and glossy fiber, which if properly prepared produces a fabric greatly resembling silk. If the production of this fiber were made the principal industry, it might be that the extraction of the rubber from the stalks would furnish a profitable by-product.

FIG. 2—ASCLEPIAS SYRIACA. FRUITING PLANT OF COMMON MILKWEED

(Photograph by Miss E. M. Kittredge, Spring Valley, N. Y.)

The great *Apocynaceae* family yields a varied series of products, among which are the *Landolphia*, and *Funtumia* rubbers of Africa. It would be expected that the American representative of the family should also be rubber producing. The latex of the well known Indian Hemp or Canadian Hemp (*Apocynum Cannabinum*) contains (Fox, same reference as above) 2.36 per cent rubber—on the weight of latex. This latex is preferably coagulated by acetone, and yields a strong black rubber of very fair quality. The root of this plant yields apocynum, which drug is used in medicine. The bark is strong, fibrous and tough, and was formerly highly valued by the Indians for bow strings. Unless very profitable by-products can be developed from these two plants their value as rubber producers is practically nil.

The Pingue plant, *Actinella Richardsonii* (Fox, *India Rubber World*, 1913, page 467), is related to Guayule, and is found in New Mexico and southern Colorado. It differs from Guayule in that the roots contain the rubber and the tops furnish slips for planting. This plant grows in a deep, sandy soil and the root contains about 7 per cent of a good grade of rubber.

There are many other plants which bear a small quantity of rubber, but to date only Guayule and Pingue have proved profitable.

Chicle contains about 17 per cent of rubber, and has been proposed from time to time as a possible source. This gum belongs to the rubber family, and is secured from the latex of *Achras sapota*. The trees grow in Central and South America, and the latex is secured by very crude methods, which in the advent of a great demand would be liable to permanently destroy the supply. However, scientific methods of tapping could be introduced, and the gum harvested in an economical manner.

But the unfortunate part of this idea is that chicle is already the basis of a very profitable industry, namely, chewing gum, the average retail value of which is about \$30,000,000 per year, in this country alone. The customary 5-cent package weighs about 1 ounce, and contains about $\frac{1}{4}$ ounce of chicle. By a little calculation it is evident that about 600,000,000 packages are sold annually, which represent, say, 10,000,000 lb. of chicle, valued at 60 to 65 cents per pound. On the basis of 25 per cent, this means an annual consumption of about 40,000,000 lb. of chewing gum, the retail value of which is about 75 cents per pound. Since the other ingredients are relatively cheap, the profit on chicle importation must be enormous. In view of the above, any process for the production of rubber using chicle as a base seems to me to be analogous to the substitution of gold for steel in rails. Another point on the subject is that should such a proposition be feasible, we would still be dependent upon a foreign country and upon water transportation, neither of which is considered desirable from a preparedness standpoint.

However, in case of absolute necessity the public can be relied upon to follow up a gigantic salvage campaign, which could furnish us with 1,700,000 lb. of rubber at the bare cost of extraction. Might not this be a good idea for the rubber chemist to investigate even in peace time?

Let us now consider the advisability of establishing plantations in the Philippine Islands. From the very start we must realize that such a procedure would only give us peace time relief, for in the event of war our navy could not be expected to keep the lanes of the sea absolutely free from hostile vessels. At the very best our losses would be considerable. That this is true we have only to consider England's navy, the grandest and mightiest in the world, yet it cannot rid the ocean of

the dreaded "Unterseeboot." An absolute blockade of our ports is rather remote. Unless America should face a coalition of enemies we have nothing to fear. Only Great Britain could make us really uncomfortable. I am thinking now of the time when our great naval and military program will be well under way. At the present writing—but why be pessimistic?

I have reliable information that the greatest drawback which has heretofore prevented capital from planting in the Philippines is the extreme uncertainty of the situation. It has been the obsession of one of our political parties to set these islands adrift—at such time as they seem fit to rule themselves.

Now, is this the right attitude? Let us think of the Philippine Islands one hundred years from now, or the thousand years some people say will be needed before this desideratum is reached. Let us consider that at this time the Filipinos will be capable of self-government. Will they as a people require any more freedom than the people of New Jersey or of Kansas? The desire for freedom and liberty is a natural one, but are the people of these states any less free because of their allegiance to the United States of America? As the Filipinos progress in the study of civil government, will they not appreciate the virtues of a union with the United States?

By all the laws of right and justice the Philippines belong to America. We delivered them from the curse of a decaying empire, saved them from oppression, and paid in gold for their acquisition.

Has the American rule been tyrannical? Have we despoiled their people? Not at all. We have kept order, when necessary, by force of arms. That was our duty, the same as it is the duty of every city police force. We could not permit a state of anarchy to exist such as now exists in Mexico. We abolished an antiquated land system, not by force of arms or by imperial decree, but by some millions of American money paid for friar lands. We sent good American teachers and set up a school system, the working of which has been little short of marvelous. In every way American occupation has been a good thing for the islands. We certainly deserve some gratitude from the Filipinos. We have given them our blood, our money, our brains, and our time. Why should they not appreciate these things, and be content to remain under our flag? The mutual benefits would be very great.

With the Philippines definitely decided as part of the United States, American plantations there would be very good business. On the other hand, should the

islands be set free there is a possibility of an outbreak of anarchy. Anarchy and business never go together.

It would be well for us now to pay attention to the work of the British planters in the Far East. They have used great skill, patience and foresight. They had to contend with the most adverse conditions, but with characteristic British energy they have created an industry, the magnitude and earning power of which we little appreciate. The establishment of plantation rubber is one of their masterpieces.

In 1877 H. A. Wickham smuggled some 70,000 seeds of *Hevea Brasiliensis* out of Brazil. They were planted in London, and the slips sent on to Ceylon. This was the beginning of an industry that supplied in 1915 about 100,000 tons of crude rubber—68½ per cent of the world's supply.

The major part of the planting has been done in the Federated Malay States, and in Sumatra. To date the capital outlay has been enormous, amounting to about \$320,000,000. In the early days interplanting was resorted to to help carry the load. Tea and coffee found the greatest favor. As the Hevea trees came into bearing these quick crops were gradually discontinued.

The present custom as to planting is as follows: The jungle is cut down and the ground thoroughly drained and cleaned of all old roots, which if left to decay would be liable to cause root disease in the young trees. The seedlings, which have been carefully raised in nurseries under the direction of competent foresters, are set out about 120 to 150 to the acre. As the trees grow they are gradually thinned out until

SKETCH SHOWING
HALF-HERRING BONE
SYSTEM

only about 50 to 80 per cent are remaining. This number depends considerably upon the depth of the soil. As would be expected only the poor trees are removed. It is entirely a matter of survival of the fittest. From the time the tree is set out until tapping, which is ordinarily begun in the third or fourth year, about all that is necessary is to keep the plantation weeded, and to turn over the soil around the base of the tree about once a year. It is customary to fertilize with lime and manure, and on poor soils to use a little sulphate of ammonia. Pruning is resorted to when necessary, and all cuts are covered with some preparation to protect the tree from insects.

The tapping problem has received considerable attention. It is quite obvious that maximum ultimate yield per acre is much to be preferred to maximum yield per tree per year. The parts of the tree are: The pitch, wood, cambium, the cortex and the bark. It is necessary to cut through the bark and almost through the cortex, which contains the latex cells. The cambium is a very sensitive membrane, and must not be injured in any way or a wart will form which may kill the tree. The cortex is only about 12 mm. thick, consequently the cuts are of an average depth of only 10 mm. in the cortex.

The half herringbone system of tapping has proved most satisfactory. It was formerly the idea that the more cuts in a tree the greater the yield per tree per year. Unfortunately this did not give the greatest total

yield per acre in the long run. By a long series of experiments the present half herringbone quartering system has been evolved. When first tapped, the tree is laid off into quarters, and in only one quarter are two narrow cuts made, these leading to a central channel. The latex flows down these cuts into the central channel, and down this to an earthenware cup. The tree is tapped nearly every day by removing a very thin shaving of bark and cortex. After a month's time the cuts will have widened only about an inch. By the end of the year they will be together. The next year the operation is repeated on the opposite quarter; the third year cut is made on an adjacent quarter, and that

SKETCH SHOWING QUARTERING SYSTEM

of the fourth on the opposite one to this. By the fifth year, which is the eighth or ninth of the life of the tree, the bark covers the first section and tapping is resumed on the same quarter that was first used. Tapping is really a fine art, and the Malay has proved quite efficient and satisfactory at it.

The latex is carried to the coagulating stations, strained to remove all sticks and other dirt, as well as such lumps of naturally coagulated material as may be present. It is then poured into shallow pans and coagulated by means of acid. Acetic acid finds the greatest use owing to the wide range in permissible concentration to completely precipitate all the rubber. With sulphuric acid this range is only 0.1 to 0.2 per cent, while with acetic the concentration may vary from 0.09 to 0.8 per cent, thus making its use very nearly fool-proof. Other acids can be used such as tartaric, oxalic, formic, etc. Chinese vinegar also sometimes finds application.

After allowing the coagulum to settle, usually over night, the surface scum is removed, the rubber taken out and worked into slabs, which are left with considerable latex inclosed for about six days. This procedure is to give the proteins in the rubber and in the latex an opportunity to decompose into certain undefined substances which give a rapid curing rubber. The work of Eaton and Grantham (the Agricultural Bulletin, Federated Malay States, vol. 3 and 4, various numbers) on the subject of "Variability" has thrown a very great light on the subject of coagulation and the properties of rubber secured under different conditions.

Plantations are at present producing only three important grades, namely: Pale Crepe, Smoked Sheets and Brown Crepe. Pale Crepe is the very finest of their product, and on the largest plantations now amounts to from 70 to 80 per cent of the total output. In some districts it is the custom to add a little sodium sulfite to the latex before coagulating, but this is no longer an absolute necessity, since with care and cleanliness a very satisfactory rubber can be secured without it.

After the slabs have been stored six days they are milled, washed, and hung in a loft to dry for two to three months, following which the thin sheets are ready for packing.

If smoked sheets are to be prepared the rubber is put through the same process as above and the sheets hung in a smokehouse where a slow fire of coconut husks is kept burning. After ten to fifteen days the sheets are

removed and the soot brushed off, when they are ready for packing.

Brown Crepe consists of surface skimmings, natural coagulated lumps, and the better grades of scrap. Some plantations make only Brown Crepe, but these are not many. There are also numerous grades of "scrap," which make up but a very small part of the total output.

The yield from one tree is not large, varying from three to seven pounds, depending upon the age of the tree. Arden (India Rubber Journal, 1916, page 199), states that trees properly cared for will yield about 7 lb. per year when 10 to 12 years old, which, on the basis of 60 trees per acre, amounts to 420 lb. per acre per year. He also estimates the "all in" costs on trees yielding the above amount. He places it at 9.5d., or about 19½¢. per lb. He remarks also that with rubber selling at a shilling a pound (*i. e.*, about 24½¢.) a profit of 2½d. per lb. would be realized, or £4 7s. 6d. (\$21.29) per acre, which would be sufficient to pay a dividend of 10 per cent on an acre capitalized at £43 15s. (\$212.91). Mr. Arden does not fear any speedy drop in the price of crude rubber, but simply gives these figures to show the soundness of the business.

It must not be taken that the trees yield anything near like 420 lb. per acre when first tapped. Taking the average number of trees per acre from the time of planting to the 10th or 12th year as 100, the schedule is approximately as follows:

1st year of tapping.....	70 lb. per acre
2nd year of tapping.....	140 lb. per acre
3rd year of tapping.....	*250 lb. per acre
4th year of tapping.....	325 lb. per acre
5th year of tapping.....	375 lb. per acre
6th year of tapping.....	400 lb. per acre

*This is the maximum yield in some parts of Ceylon.

In spite of war conditions the world's consumption of rubber has increased by 20 to 30 per cent. It is estimated that the Far East has produced in 1916 about 140,000 tons, an increase of 40,000 tons or 40 per cent over the 1915 yield. There is absolutely no such thing as flooding the rubber market. As the quality available increases, the applications multiply and no one can see the end.

To go back to the Philippines, *Hevea Brasiliensis* has been found to grow most satisfactorily in a belt 10 deg. on either side of the equator. This belt includes the Philippine province of Moro, whose most northern point is about 9 deg. north latitude. This district includes the island of Mindanao, its tributary island Basilan, and other smaller islands. It is a truly tropical region, and very well adapted to planting. The soil is equal in every way to that of the best rubber-growing district in the world. The rainfall is about 100 in. annually, and is evenly distributed. The temperature rarely exceeds 92 deg. Fahr., and what is more important the province lies outside of the typhoon belt. This is a distinct advantage, since storms often wreak great havoc in Ceylon, Sumatra, and others of the British possessions in the Far East.

There have been small experimental plantations started in this district. About 6000 acres are now under cultivation. The planting averages about 90 per cent Hevea, and 10 per cent Castilloa. Some Ceara has also been planted, but it was found to be unsatisfactory.

The Agricultural Department of the Moro province has published the following figures, which show the relative costs of bringing new land under cultivation in the island of Mindanao, and in various other islands of the Far East.

Moro	\$50.94 per acre
Sumatra	73.60 per acre
Java	109.94 per acre
Federated Malay States.....	137.42 per acre

The relative costs of upkeep are given as follows:

Moro	\$18.00 per acre
Sumatra	20.00 per acre
Java	23.00 per acre
Federated Malay States	29.00 per acre

Taking all in all, it is estimated that an acre of land may be prepared, planted, and brought to bearing in the fifth year for \$150.

The labor situation is good, the average Malay is quite intelligent, and shows evidence of a one-time civilization of no mean sort. The stories of the ancient Malay empire may not be as mythical as is commonly supposed, but laying all that aside he can be trained to perform the most skillful operations, and the tapping of rubber trees is but one of these. He is reasonably industrious, and if properly handled proves quite satisfactory. The daily wage prevailing ranges from 20 to 30 cents. If anything be needed to make the proposition more lucrative, it is found in the large tracts of government land which can be secured quite reasonably.

Besides the island of Mindanao, the island of Mindoro has also been the scene of considerable experimental planting, with a fair degree of success notwithstanding the fact that it lays at about 13 deg. North latitude. Experiments in the Philippines have languished for want of capital. There are great possibilities there, and what is most needed is for the American people to get behind the proposition and push.

Some experiments have also been made in the Hawaiian Islands. Up to 1913, the date last reported, about 1500 acres were planted in rubber. Of this area about 300 acres are planted in Hevea, and 1200 in Ceara. (*Manihot Glaziovii*.) The latter has been found to be most satisfactory in this region, notwithstanding the fact that the tree drops its leaves annually and must therefore be left alone from February to May.

The soil is porous, the rainfall about 100 to 200 in. per year. The planting has been done in the Nakiku district of the island of Maui, and in the Puria district of the island of Hawaii. A fair degree of rubber has been produced, but considering everything it is the writer's opinion that the place for American plantations is the Philippines rather than Hawaii.

It has been my aim to present the possibilities of an American crude rubber business. To my mind we must resort to Guayule if we would produce rubber in any quantity within our borders. This step is absolutely necessary as a preparedness measure. Moreover, there is money in it. Experiments along this line are now almost completed, and in the very near future we can expect cultivated Guayule to take its place among commercial rubbers.

A plantation industry in the Philippines would be entirely a good business proposition, if certain parties would quit playing schoolboy politics and recognize the economic needs of the nation.

At this time there is strong talk in England and in France of replacing the embargo on crude rubber exports. The claim has been made that the Rubber Club of America has failed to live up to its agreement in allowing the submarine Deutschland to obtain two cargoes of rubber from this country. This agreement has to do only with rubber obtained from British and French possessions, and the Deutschland's first cargo is reported to have been obtained by certain parties in the open market. Very probably some British rubber made up that cargo, but by that act those parties are forever barred from further purchases, and have brought upon themselves the ostracism of every American rubber man. The second cargo was obtained from the Dutch East Indies, and the British Government has nothing whatever

to say in the matter. The Rubber Club of America has lived up its agreement to the very best of its ability, but having no police power it cannot prevent occasional infractions of the rules. It can and does say that such parties as break the rules once can never do so again.

The possibility of the restoration of the embargo makes me as an American wish to go them one better, and grow our own rubber.

The subject of synthetic rubber will be taken up in a subsequent paper.

Training the Works Chemist

By Frank E. Lathe,

Chief Chemist, Granby Cons. Mining, Smelting & Power Co., Ltd

I well remember my surprise, when, on securing a position as chemist shortly after graduating, I learned that I would be expected to do each morning in about two hours, work that would have taken me more nearly two weeks in the college laboratory. Probably many another college man has had a similar experience, even leading him to question the practical value of his training. However, I think, it will be generally conceded that the chief value of technical training lies, not in the precise methods taught, but rather in the fundamental principles of chemistry on which all methods must be based, and on a general familiarity with the various operations to be performed. But the fact that theory is more important to the college man than practice is a poor reason for not teaching the student to make the most of his laboratory periods, and a little applied common sense—scientific management, for those who prefer the phrase—will not only fit him better for the practice which will eventually become his daily work, but will also enable him to accomplish far more in the limited hours to be devoted to practical work at college.

Many teachers of analytical chemistry have had no experience in work of this kind under commercial conditions. They may owe their appointment to their ability to make very accurate analyses, or to the fact that they were capable research chemists. If so they are scarcely to be blamed for worshipping the god of accuracy and shunning the demon of speed—but how often the furnaceman requires to know in a few minutes the approximate sulphur content of his steel, or the grade of his copper matte, while accurate results given him the next day would be worthless! In practical work accuracy must frequently be sacrificed to speed, and while some of the quick methods are already taught in our colleges I want to enter a plea for more instructors who have made good under actual working conditions, and who will therefore direct the energies of their students along the most practical lines. In the case of mining and metallurgical students this may often be accomplished by placing all quantitative analysis under the complete control of the metallurgical department.

I will now indicate some of the points which I believe might well receive greater emphasis in the training of the chemist:

First, the acquirement of habits of thoroughgoing cleanliness and systematic procedure. I see held up in horror the hands of many a man who has for years taught—by example if not by precept—that a little of dirty beakers, retorts, test tubes, etc., is necessary to create a proper "atmosphere" for work. But of the men whom I have observed in practice the most efficient were those whose work was reduced to a system, who kept every reagent bottle and piece of apparatus clean and in its appointed place, and who consequently performed their work quickly and well. Surely cleanliness and order are two of the most important factors in the

achievement of analytical success, and the first day of instruction in practical chemistry is not too soon to begin training along these lines.

Second, a general survey of the work to be done by each student during the college year, and the drawing up of a systematic plan of operations; a study of the different determinations, with a view to running several at one time, in order that every moment may be fully occupied.

Third, not only the most accurate methods required in practice, but, even to a greater extent, the quick methods. The student should know the error permissible in such work, and should govern his weighing, filtration, etc., accordingly. Many a college graduate required to determine the iron in a slag, with an error limit of one part in 100, will weigh his sample to one part in 5000, and actually spend longer in the weighing than a practical chemist would require for the determination. This is on a par with reporting to hundredths of a per cent results not closer than one per cent to the correct value.

Fourth, the helps to rapid work. These consist of both mechanical devices and a knowledge of conditions favorable to the performance of the various operations. College laboratories spend much for expensive apparatus which is seldom used, while but a small sum would be required to provide the students with numerous devices which would greatly facilitate rapid work, and which are to be found in most works laboratories. Descriptions of many such are to be found in the technical publications.

As an example of the desirability of studying conditions I will mention three helps to rapid filtration which were not sufficiently impressed upon me at college: hot precipitation, with subsequent boiling; the use of the suction pump for some precipitates, and its avoidance for others; the selection of the proper filter-papers for various precipitates and conditions.

Fifth, the development of the student's judgment, when he has gained some degree of familiarity with analytical methods. Though required to make analyses for definite elements or radicals, he should be allowed considerable liberty as to the choice of method. This choice is extremely important, being influenced by the degree of accuracy required, the time allowed for the determination, the modifications to be made in the presence of interfering elements, or by the fact that several determinations are to be made in the same portion.

To illustrate this point, the electrolytic method for copper is rightly valued for its accuracy, but as described in a leading text-book the presence of lead, ar-

senic and bismuth is assumed. The chemist who would deliberately choose that method, as described, in the known presence of these elements, is in dire need of instruction in the choice of method.

Something like the following might be used as a guide in the determination of copper:

(A) For accurate work.

(1) When ores do not contain interfering elements, electrolytic.

(2) In presence of As, Bi, etc., iodide.

(B) For approximate work.

(1) Ores, slags or tailings under 1.0 per cent Cu, colorimetric.

(2) Mattes, cyanide.

(3) Medium or high grade ores.

(a) No Zn, etc., cyanide.

(b) Zn, As, etc., present, shortened iodide or permanganate.

(c) If no interfering elements, electrolytic, as little manipulation is necessary.

Sixth, the value of considerable familiarity with such determinations as those of silica, sulphur and the common metals (both accurate and approximate methods) rather than a single determination of a very long list of elements. The chemist who can determine a few elements well should be able, with the assistance of a good text-book, to get satisfactory results for any. The intensive training will make a deeper mental impression and produce a greater self-confidence than the extensive. At present the young graduate is likely to think that he has been taught the best method for each element, but he may find that his method is far from the best under the practical conditions which confront him.

PRACTICAL APPLICATION OF THE ABOVE SUGGESTIONS

No cast-iron rules can be laid down as to which methods or procedure should be followed in works laboratories. In each plant the chemist must be governed by local conditions in all that he does. For this reason, if for no other, the example which I will give of how the principles enunciated above have been applied in the laboratory of one copper smelter is not intended to be taken in any sense as a model, but simply as an illustration. And it is probable that another series of chemists might have differently arranged the same work to secure equal or greater efficiency. Of the succeeding chemists who have contributed towards the goal of greatest speed with all the accuracy necessary I wish to give especial credit to George M. Lee.

Determinations and accuracy required: Cu on sixteen samples of blast furnace slag to 0.02 per cent; SiO_2 , Fe and CaO on an average of the same to 0.2 per cent; SiO_2 (insol.) to 0.5 per cent and Cu to 0.1 per cent on each of nine samples of converter slag; Cu to 0.5 per cent on sixteen samples of matte.

Plan of work: Errors will be allowed in weighings, but in no case must these exceed one-fifth the permissible error in result. Cu in blast furnace slags, running about 0.20 per cent, will be estimated by color, in converter slags (1-2 per cent), and mattes it will be determined by the cyanide method. Only one evaporation is required for SiO_2 ; the result on the blast slag will be about 0.6 per cent lower than the true SiO_2 , those on converter slags a little high, due to imperfect decomposition. Fe will be by the bichromate method—the permanganate would be equally good—CaO by the permanganate. The SiO_2 and CaO are the longest determinations, so will be started first and given closest attention. All the others are fairly short. Only sixteen cyanide burettes are available, so mattes and converter slags will be run separately for Cu.

Fig. 2 Wash Bottle

Fig. 1 Sprinker
Made of tin or lead

Fig. 3 SnCl_4 Bottle
To use, invert

For wash bottle, bore three holes in rubber stopper, as shown, using wet borer and starting holes at small end. For valve, tie rubber tubing securely to lower end of mouthpiece, fold over loose end and tie tightly. Cut two quarter-inch vertical slits on opposite sides—one is shown. Tubing in bottom allows emptying bottle without blowing air over. Wrap neck with wet sheet asbestos, covering with layer of heavy cord, drawn tightly. To use, place thumb over open tubing, blow, then remove thumb to release pressure. Constant blowing not necessary.

Mechanical equipment: (That which is in common use in all laboratories will not be mentioned.) Sufficient three-heat electric hot plates to accommodate all the work at once. Overhead heater for water, with bottom outlet, rubber tube and glass tip for washing precipitates. Overhead tank for cold water, with siphon outlet and $\frac{3}{8}$ -in. rubber tube terminating in sprinkler device (Fig. 1) for making quick dilutions in casseroles and beakers without spilling liquids in latter. Overhead ammonia bottle with siphon, and rubber tube reinforced with friction tape. Special wash bottle (Fig. 2), with valve to prevent hot water or acid fumes getting into mouth of operator and to keep up pressure without continuous blowing. Special bottle (Fig. 3) for the addition of SnCl_4 in small quantities. Cyanide burettes without pinchcocks, but with rubber tubing containing glass beads as valves, and glass tips. Siphons for filling burettes from elevated bottles or carboys. Titration plate of paraffin and zinc oxide—cleaned, when necessary, with gasoline. Shaving-stick box with small holes punched in top, containing crystals of $\text{K}_2\text{FeC}_2\text{N}_6$ for making up small amounts of solution for Fe titration. Dropping bottle, painted black, for the preservation of easily decomposable "slag acid" (see below), and for the addition of small quantities of it when surplus acid has to be evaporated— SiO_2 determinations. Wooden tray to hold eighteen 400-c.c. beakers or equivalent. Enamelled saucers, in place of sample envelopes, for matte and slag samples, each bearing pasted label showing number of furnace or converter and shift to which sample belongs.

Routine of operations: Place on tray ten 3-in. casseroles, with watchglass covers, one 250-c.c. beaker, and nine 400-c.c. beakers. Out of each blast furnace slag sample take small spoonful of slag, mixing well together on rolling cloth. Weigh out of this average 0.5 gm. (within 0.001 gm.) into 250-c.c. beaker for Fe and 0.5 gm. (within 0.0005 gm.) into casserole for SiO_2 . Weigh 0.5 gm. (within 0.002 gm.) of each of converter slags into casseroles for SiO_2 , and 2.0 gm. (within 0.01 gm.) of same into 400-c.c. beakers for Cu. From dropping-bottle add to each casserole 1-2 c.c. "slag acid" (mixture of four vols. HNO_3 , one vol. HCl , two vols. H_2O), cover and set on plate at high heat. Into each 400-c.c. beaker pour 10-12 c.c. HNO_3 , and set on plate at medium heat without covers. From wash bottle pour 5 c.c. boiling H_2O into 250-c.c. beaker, and while rotating beaker on hot plate add slowly about 5 c.c. HCl . With glass rod loosen any SiO_2 from bottom and heat one minute longer. Remove, add three drops SnCl_4 , dilute to 100 c.c. with cold water, add 25 c.c. saturated HgCl_2 solution. Let down solutions in all burettes to zero. Place beaker of saturated oxalic acid solution on asbestos on plate. Partly remove covers from casseroles, now almost dry. Shake a few crystals $\text{K}_2\text{FeC}_2\text{N}_6$ into beaker, add 25 c.c. H_2O , transfer to dropping-bottle, put dozen drops on spot plate. Titrate Fe—solution reading directly in percentage. Put eighteen colorimetric bottles under funnels and fold a 15-cm. S. & S. No. 595 filter paper into each funnel, afterwards moistening. Remove dry casseroles from plate. To each 400-c.c. beaker on plate add from sprinkler 20-30 c.c. cold water (making cool enough to handle with bare hands), remove, dilute similarly to 200 c.c., add 10-12 c.c. NH_4OH (from siphon), stir with rubber-tipped glass rods (using both hands), place under KCN burettes, add 1.0 c.c. to each, again stir. Pulverize well the dry residues in casseroles, replace on plate. Make second addition of KCN—in amount according to depth of color. On tray place eighteen $3\frac{1}{2}$ -in. casseroles, into each weigh 1.0 gm. (within 0.01 gm.) furnace slag, including as standards two previously determined by

electrolysis to contain 0.19 and 0.21 per cent Cu. To each add 10 c.c. HCl and set on plate at medium heat. Remove silica casseroles. Make third addition of KCN (little will be required). On tray place sixteen 400-c.c. beakers and into each weigh 0.5 gm. matte (within 0.001 gm.). To each color copper casserole add 2-3 c.c. HNO_3 , turn heat off plate. To each matte beaker add 10 c.c. HNO_3 , and set on plate at medium heat. To each SiO_2 -casserole add 10 c.c. HCl , leaving off plate. Make final addition of KCN, if any required, read burettes, adjust to zero. Attach filter pump, fold carefully ten 11 cm. No. 1F Munkell's filter papers. To each SiO_2 -casserole add 25 c.c. H_2O , set on plate at high heat. Dilute colorimetric determinations to 100 c.c. each, stir with rubber-tipped glass rod (use same for all), loosening well from bottom. Slightly dilute mattes (to cool), remove from plate, dilute to 200 c.c. To each colorimetric casserole and matte beaker add NH_4OH to precipitate Fe and 5 c.c. additional. Stir all well. Place matte beakers under burettes. Filter silicas by suction, washing each once with HCl from dropping bottle or wash bottle and three times with hot H_2O . Place silicas in annealing cups. Transfer first filtrate (from blast furnace slag) to 400-c.c. beaker, retain others in suction flask. To first add NH_4OH till alkaline and 5 c.c. additional. Place on plate at high heat. Place annealing cups in front of muffle—just below red heat. To each matte beaker add KCN, stirring constantly, till the color changes to light brown. Pour hot oxalic acid solution into boiling filtrate from SiO_2 till CaO is precipitated as oxalate. If very little acid be required, either add 1.0 gm. ammonium oxalate or reprecipitate Fe with NH_4OH and redissolve in oxalic acid. Move annealing cups to hottest part of muffle. Make second addition of KCN to mattes, according to color. Filter slags for Cu into colorimetric bottles, washing precipitates twice. Make third addition of KCN. Filter CaO through 12.5 cm. Munkell's No. 1F paper, washing nine times at intervals. Put 100 c.c. H_2O and 10 c.c. H_2SO_4 in original 400-c.c. beaker and set on hot plate. Fill colorimetric bottles to mark and shake. Remove annealing cups from furnace. Compare Cu in slags with standards. Make last addition of KCN to mattes (if any necessary) and read burettes. Drop filter containing calcium oxalate into boiling H_2SO_4 solution and titrate at once with KMnO_4 . Weigh silicas.

An hour and a half is good working time for one chemist on the above, though it has been done occasionally in an hour and a quarter. While this is not as fast work as done by many chemists running determinations of one kind only, it may be sufficiently in advance of that of the student to illustrate the point that I wish to emphasize—that by the adoption of quick methods, the use of convenient equipment, the concurrent determination of several elements or radicles, and a careful planning of all work, it is possible to accomplish considerable even in a time as short as one of the college laboratory periods.

In conclusion, I will state my belief that one year's practical experience before or during his college course will give the average man a new sense of the opportunity which is his during his student life, and the growing insistence of instructors upon such practical work is one of the encouraging signs of progress in the training of technical men.

Grand Forks, B. C.

Government Radium Tests.—In October, 1916, the United States Bureau of Mines received the largest quantity of radium to be tested for a single month. The total value of the radium was \$77,000. Up to date the aggregate value of radium tested by the bureau is above \$1,000,000.

Synopsis of Recent Metallurgical and Chemical Literature

Metallography

Grain Growth Phenomena in Metals.—In a paper to be read before the members of the American Institute of Mining Engineers, at the February, 1917, meeting of this society, at New York, ZAY JEFFRIES discusses factors influencing fast growth phenomena, fast growth phenomena in low-carbon steel, and effect of cold deformation on uniformity of orientation of original grains.

Under the first heading come the effect of rate of heating, the resistance to grain growth, influence of grain size prior to deformation temperature and deformation gradients, and the influence of the thickness of the sample. The conclusions drawn on the effect of the rate of heating are: The time factor is always a governing factor in the first stage of grain-growth; if the time of heating is short, the germinative temperature is raised. The formation of large grains in metals may occur at relatively high temperatures when the rate of heating is rapid.

The resistance to grain growth is divided in two parts: First, the resistance offered by the pure predominating constituent and second, the resistance offered by impurities. At the germinative temperature the present of impurities favors the formation of coarse grains. As the resistance to grain growth increases, the germinative temperature increases and the time necessary to form large grains decreases rapidly. As a general rule, other conditions being equal, the finer the existing grains at the germinative temperature, the greater will be the tendency toward selective grain growth.

In a pure metal with a given amount of cold deformation, the grain size before deformation will have a marked effect on the selective grain growth during annealing. If the initial grain size is large the grain fragments formed during annealing will also be large and vice versa. If the grains are initially large the fast growth phenomena may be almost completely masked. The formation of large grains at the germinative temperature is dependent upon the evenness of the grain size with a temperature gradient or an even temperature with a deformation gradient or any combination of the two. The difference in temperature of recrystallization furnishes the cause for selective grain growth due to deformation gradients. When the total average cold deformation exceeds about 30 or 40% reduction in area of the metal, the number of germinative grains formed during normal muffle heating may approximately equal the number of equilibrium grains for the maximum temperature reached during annealing. The effect of thickness of section on grain growth in metals is general. In wires of small diameter the author has found two regions in which fast grain growth takes place. One occurs at the germinative temperature and the other occurs at most any temperature above that, the time varying inversely as the temperature. At the second temperature the large grains form invariably near the surface of the sample. The formation of large grains in wires of small diameter may be invariably checked by the introduction of impurities, such as non-metals. The introduction of impurities has the same effect as lessening the diameter of the wire.

The author then applies the above mentioned facts to the theory of grain growth in low-carbon steels. Here, he states, that the formation of gases in metals are also to be considered as offering resistance to grain growth. This is due to the fact that gases in solution

or mechanically entrapped affect the annealing temperature after cold deformation, as Rose and Phelps have demonstrated.

According to Prof. Howe, the uniformity of orientation after cold deformation is greater within the individual original grains than between adjacent grains. This, Jeffries claims, is true for the majority of the cases, but it also must be considered, that in cold-deformed metals there is sufficient difference in orientation within the original grains to be the chief cause of recrystallization on annealing. That this may generally be observed is due to, first, that the diameter of the individual grains in which we can study etching pits is usually not more than 0.0002 in. and, therefore, any difference in orientation of the grains is not readily visible; and secondly, the sections which are usually examined in deformed metals are the most conducive to similar etching tints.

Lead

Matte Granulation at Herculaneum, Mo.—S. PAUL LINDAU and HENRY B. SMITH will present a paper under the above title at the February, 1917, meeting of the American Institute of Mining Engineers at New York. The St. Joseph Lead Co., at Herculaneum, Mo., have decided to granulate the matte obtained at that smelter in order to eliminate a large amount of labor and save the crushing.

The matte is tapped into 6 cu. ft. iron ladles. These are transported to the granulating plant by electrically driven overhead cranes. The matte is received in a cylindrical container, which in reality is a specially devised Traylor converter without the tuyeres and has a 20 in. opening at one end for the flue and oil burners. It may be tilted and is lined with a 9-in. lining of magnesite brick. The consumption of 18° to 20° Be. crude oil is 250 gal. per 24 hr. or 2 to 2½ gal. of oil per ton of matte granulated. Thirty lb. of air are supplied per burner for atomizing the oil.

The liquid matte is granulated by pouring it through two superimposed flat jets of water shooting horizontally into a concrete tank lined with cast-iron plates. The stream of matte is accurately directed on to the jets of water by means of a pouring box. This box is lined with common brick and the matte is poured into it by revolving the container. A dewatering drag conveyor removes the granulated matte from the tank, the floor of the latter sloping at an angle of 30° towards the trough in which the conveyor operates. The conveyor elevates the matte over the slag track and discharges into railroad cars, which are weighed, the contents sampled and dumped into roaster bins. A V-shaped settling box takes the overflow of the tank proper and saves the coarser slimes, while the fine slimes are collected in a series of settling tanks. An excelsior filter finally cleans the water from the end settler, which then goes to the circulating pond. Two series of settling tanks are used, one lying idle while the other is in operation.

Under the old regime the cost of matte handling including screening, was \$1.43 per ton. Granulation costs only \$0.75 per ton, thus giving a saving of \$0.68 per ton of matte granulated. The following two tables will be of interest:

Summary

Matte granulated per 24 hr., tons.....	100
Rate of pouring, cubic feet per minute.....	3.2
Oil consumed per 24 hr., gallons.....	250
Oil per ton of matte granulated, gallons.....	2.5
Water used per minute (under head of 40 ft.), gallons.....	100

Screen Analysis on Granulated Matte

Inch-Mesh	Per Cent.
On 1.....	5
On 3/16.....	4
On 1/8.....	14
On 1/16.....	35
Through 1/16.....	42

Pitch

Coal Tar Pitch.—*The Iron and Coal Trades Review* (London) gives the following information on pitch taken from a circular sent out by the London Coke Committee: "The prevailing condition of scarcity and high cost of steam coal naturally direct attention to the fuel value of the huge accumulations of pitch which now tend to encumber the working up of high-explosive munitions of war at coke oven, gas works and other tar distilleries. The total yearly production of pitch at the 248 tar works registered in 1915 has been estimated at over 1,000,000 tons. With the sudden closing of the Continental market in August, 1914, and the continued restrictions on export trade, hitherto the chief method of disposal, the outlook for pitch and, incidentally, coal tar in the near future is extremely problematical. Prospective new outlets for use in gas and briquette making have not yet materialized to any appreciable extent, and with the increasing demand for coal tar derivatives which may be confidently anticipated, the possibilities of the fuel field as an outlet for surplus pitch should be critically examined. Considered as a fuel for steam boiler and other furnaces, pitch has distinctly attractive features. Not only is its calorific value—viz., 15,000 to 15,500 B.t.u. per pound—higher than that of the best quality Welsh steam coal, but its present price in the Midlands and London district respectively is only about one-third to one-half that of such coal; moreover, it is practically pure carbon, and ash and moisture free, so that in whatever proportion it may be added to other staple fuels, more than an equivalent amount of such fuel may be released for sale or export. The relatively high price realized for pitch has in the past naturally precluded its direct use as fuel. Experience in and special appliances of proved utility for its use directly as fuel are therefore lacking, or at least unknown to the would-be user. Recent experiments in this direction which have had for their object the provision of a simple and inexpensive appliance in the form of a specially designed firebar are therefore of some interest. The chief difficulty experienced in attempting to burn pitch has been the low fusing and volatilizing temperature common to all pitches and the consequent tendency to separate carbon in the form of dense smoke. Compared with average bituminous coal containing 23 per cent volatile matter, pitch contains about 55 per cent, the remainder being practically pure amorphous carbon. The claim is made that by means of this special firebar, coal tar pitch may be consumed in conjunction with coke with considerably less than the ordinary amount of smoke observed at the chimney of a coal-fired boiler. The *modus operandi*, which has been tried with some success in certain gas works boilers, is to substitute a number of "pitch" bars for an equivalent number of existing firebars in a boiler furnace fitted with steam-jet, forced-draft apparatus of ordinary construction. Pitch, broken to any convenient size, is fed on to the pitch bars, where the heat of the surrounding fire causes it to collect and volatilize; the rate of such volatilization being controllable by means of the special formation of the pitch bars within limits which insure practically smokeless combustion. The partially coked residue remaining after the more volatile constituents have been burned off is periodically raked onto the rear portion of grate, where its combustion is completed.

Large Sugar Beet Crop in 1916.—Preliminary returns from the beet-sugar factories indicated a production of 918,000 short tons of sugar during the 1916 campaign. The area harvested was 680,000 acres. The sugar production exceeds the highest preceding crop in 1915 by 44,600 tons.

Recent Metallurgical and Chemical Patents

Caustic Soda

Manufacture of Caustic Alkali.—A patent has been granted to EDGAR A. ASHCROFT of London, England, on a process of producing anhydrous caustic alkali by treating fused alkali metal (produced in an electrolytic cell from an alkali salt in a fused state) with ammonia in one cell to produce an amid. The amid is run into a second cell and heated with steam, producing anhydrous caustic alkali and free ammonia. The product from the second cell is run into a third cell into which the free ammonia from the second cell and steam are passed, where the reaction is completed and the ammonia dried. The dried ammonia is returned to the first cell for use again. (1,198,987, Sept. 19, 1916.)

Phosphoric Acid

Electric Furnace for Phosphoric Acid.—Improvements in an electric furnace for producing phosphorus and phosphoric acid vapors from phosphate rock are patented by INGENUIN HECHENBLEIKNER of Charlotte, N. C. (assigned to Southern Electrochemical Company). The furnace is adapted to produce phosphoric acid from a mixture of phosphate rock, siliceous material and carbon, the gases consisting of phosphorous vapor, carbon monoxide and phosphoric acid. The improvements consist in using the gases to preheat the charge and in improved cooling devices. (1,202,837, Oct. 31, 1916.)

Tungsten

Metallic Tungsten.—An electrolytic method of producing metallic tungsten has been patented by FREDERICK G. KEYES and ROBERT B. BROWNLEE of East Orange, N. J., and assigned to the Cooper Hewitt Electric Company. In this process tungsten trioxide is subjected to a temperature of 2000 deg. C., in an electrolytic bath with a rotating tungsten cathode and an anode of sintered tungsten. The electrolysis produces a lower oxide of less resistance, permitting the passage of the current readily. The crucible is of tungsten or of noncontaminating material. (1,202,534-5, Oct. 24, 1916.)

Tin

Electrolytic Recovery of Tin.—A patent has been issued to ALBERT E. BATTLE of Aldgate, London, England, on the electrolysis of tin and its salts. The process is applicable to the production of tin from ores or the recovery of tin from tinplate. The electrolyte consists of tin or a salt of tin such as the sulphate or protochloride dissolved in ortho phosphoric acid, either concentrated or dilute. The tin ore or scrap is used as the anode in this solution. For a good deposit of tin the patent states that 50 grams per liter of tin salt dissolved in 10 per cent phosphoric acid will be satisfactory. (1,202,149, Oct. 24, 1916.)

Cellulose

Electrical Treatment of Cellulose.—In a patent of ALBERT L. C. NODON of Bordeaux, France, it is proposed to treat wood or other forms of cellulose electrically in order to preserve them and increase their strength by first immersing for a short time in a solution of zinc chloride, sodium chloride or other conducting salts, and then subjecting to an alternating current of low frequency. The process is applicable to wood, textile plants, artificial silk, fabrics, paper paste, paper, etc. (1,198,867, Sept. 19, 1916.)

Electric Furnaces

Improvements in Birkeland-Eyde Furnace.—A new method of introducing and withdrawing the gas in a

Birkeland-Eyde nitrogen-fixation furnace, which is claimed to increase the output is patented by CARL O. A. DÖVLE of Notodden, Norway, and assigned to the Norsk Hydroelektrisk Kvaelfstofaktieselskab, of Christiania, Norway. In general the gases have been conducted through electric arc furnaces of the flame disk type along the whole flame surface, either introducing the gases at the center and withdrawing them at the periphery or vice versa. The present patent proposes to conduct the gases over only a small portion of the flame, as shown by the illustration Fig. 1 in which A represents the furnace, B the flame disk, C the inlet openings and D the outlet openings for the gases. A cooling coil shown at E may be used to augment the cooling effect (1,194,606, Aug. 15, 1916) in case it is desired.

Electric Arc Furnace.—According to a patent of EMIL EDWIN of Christiania, Norway, (assigned to the Norsk Hydroelektrisk Kvaelfstofaktieselskab) greater

stability can be produced in flame arc nitrogen furnaces of the Schönherr type, if no ground connections are made. The long stable arcs in electric furnaces of the Schönherr type are generally maintained between an insulated electrode and a cooled tube, which is connected directly to the flame tube and the outer parts of the furnace. Fig. 2 shows a drawing of three furnaces so arranged. The insulated electrodes are shown at D connected to a three-phase system, and the furnaces are represented by A, B and C. The flame is maintained between the lower electrodes and the interior wall of the coolers H. Previously these coolers and the flame tube were grounded. According to the present invention they are connected together by connectors I as shown but are insulated from the ground. It is claimed that this arrangement gives a better stability of the arcs. (1,193,882, Aug. 8, 1916.)

FIG. 1—ELECTRIC FURNACE FOR PRODUCING NITRIC ACID FROM AIR

FIG. 2—THREE-PHASE ARC FURNACE SYSTEM

Constant-Current Closed-Circuit Arc Welding System

Present arc welding practice is based on operation of arcs from constant-potential circuits, and since arcs operated under these conditions are unstable, it is necessary to use in series with each arc a ballast resistance.

In the early days, comparatively high-voltage circuits were used and enormous quantities of energy wasted in resistance. Later, as arc welding became of greater industrial importance, generators were constructed especially for the purpose, and the voltage was made as low as possible, until finally it has settled down to from 60 to 70 volts. Automatically controlled resistance which changes with the value of the current, permits the use of a lower voltage, but the arc still has the constant-potential characteristics.

A normal welding arc consumes about 22 volts. However, depending upon the operator and upon the work, it may vary from 18 to 28. Therefore, any voltage pro-

FIG. 1—SELF-REGULATING WELDING GENERATOR

duced by the generator in excess of this must be absorbed in resistance and wasted.

The constant-potential arc when operated in multiple with other arcs, requires a separate circuit from the generator end of the line, or at least from a point in the distribution system where the voltage regulation is close, otherwise the coming on and the going off of the various arcs will disturb the regulation to an intolerable degree.

On account of the expense of low-voltage distribution circuits for constant-potential arcs, practice has drifted toward the single-arc unit, portably mounted.

The Electric Welding Company electric welding contractors who have been in electric welding business for nearly ten years, developed in their practice a new system of arc welding, and in order to place this system on the market, organized the Arc Welding Machine Company as a separate corporation. The Arc Welding Machine Company has perfected the system now known as the constant-current closed-circuit system, which operates arcs in series.

This method has all the advantages of series distribution, namely, the size of wire is uniform throughout the system and carries a uniform current, independent of the length of the circuit as well as of the number of operators. The circuit is simply a single wire of sufficient cross-section to carry the current for one arc, run from the generator to the nearest arc, from there to the next, and so on back to the generator. Wherever it is desired to do welding, a switch is inserted in the line, and a special arc controller provided with suitable connections plugged in across the switch, whenever work is to be done. These controllers may be made portable or permanently mounted at the welding station.

The generator shown in Fig. 1 is a special machine and consists of two units. The generator proper which furnishes the energy for welding; and the regulator, which automatically maintains the current at a constant value. The regulator is excited from a separate source, and by varying its excitation with an ordinary

field rheostat, the main welding current may be set at any value within the range of the machine that is desired, and once set it will automatically maintain that value.

Each arc that is operated on the system is equipped with an automatic controller shown in Fig. 2 which serves two essential purposes as follows:

1—It maintains at all times the continuity of the circuit, so that one arc cannot interfere with any of the others when it comes on, or goes out of the circuit.

2—It controls automatically the heat which can be put into the metal of the weld.

The current through the arc, together with the size of pencil, determines the flow of metal from the pencil, and this current is adjusted by shunting any desired portion of the main current around the arc. The regulation characteristic of the arc is adjusted by a series parallel resistance, which is patented.

For a given flow of metal through the arc, the temperature of the metal is determined by the length of the arc, that is, by the voltage. With this controller, the length of the arc limited by the voltage is adjusted to suit the work and the operator, and if exceeded, the arc is short-circuited automatically and remains short-circuited until the welder is ready to begin again.

Provision is also made for stopping the arc at will without lengthening it. Therefore, with this system it is impossible to draw a long arc and burn the metal, and most important of all, the arc is not broken when the welding operation is stopped, but is killed by a short-circuit which is placed across it.

Stopping an arc by short-circuiting and limiting the heat production in the same way is also patented. A great step in advance has been made by short-circuiting the arc instead of breaking it; because it is impossible to avoid leaving a crater with pin-holes by any other means than reducing heating of the metal, and this is the most effective method of doing it.

FIG. 2—AUTOMATIC ARC HEAT CONTROLLER FOR CONSTANT CURRENT CLOSED-CIRCUIT OPERATION

On account of the fact, that the arc heat is automatically controlled and limited, it is possible to use a lower grade of labor in welding operations with this system.

The number of arcs that can be connected in series is limited only by the voltage, and up to the present time, 12 is the maximum for which machines are constructed. Fig. 3 shows the wiring diagram for a system containing three arcs.

A New Non-Corrosive Insulating Compound

A new product with desirable properties is being placed on the market by the Diamond State Fiber Company of Bridgeport, Pa., under the name of condensite-cellulac. It is made by curing fiber and condensite together in one operation and combines the properties of these two substances. It is anhydrous and non-hygroscopic and is impervious to the action of oil or ordinary acids or solvents. It also combines toughness with resistance to the temperatures ordinarily encountered in insulation work.

The chief feature of this material is that it can be made in sheets which are homogeneous and not made up of laminations. It is weather-proof and can be used in

ARTICLES MADE OF CONDENSITE-CELLULAC

apparatus subject to unfavorable conditions of moisture, oil, etc.

It is furnished to the trade in merchantable shapes—sheets, rods, tubes, etc., and is readily machined. It may be formed into very thin sheets (0.015 in. or less) with remarkable accuracy to gage, thereby furnishing an excellent diaphragm material. It is also supplied shaped to customers' specifications. The work as thus supplied is ready for use, having been hardened and made insoluble and infusible by the application of heat.

It is also possible to supply it in the soft uncured state, permitting of its being hardened in the place where it is to be used and thereby formed to fit in spaces or locations with great accuracy. Thus, for instance, gaskets for hot lines, steam, hot water, compressed air, etc., may be accurately fitted to rough flanges and cured in place by the heat of the line, or by applying a certain amount of external heat until the material is hardened.

FIG. 3—WIRING DIAGRAM CONSTANT-CURRENT CLOSED-CIRCUIT SYSTEM

Commercial and Industrial Preparedness in Foreign Countries

The whole field of commercial and industrial preparedness for foreign trade promotion, has received increased attention in every important nation of the world since the outbreak of the European war in 1914. The British Government immediately gave instructions to its consular representatives, commercial attaches, and trade commissioners in all foreign countries and the colonies to submit reports on opportunities for British trade occasioned by the cutting-off of the German and Austrian supplying markets. A vast quantity of samples of German and Austrian merchandise which had previously been supplied for use in these markets, was sent in by the British Government representatives, and was placed on display in London. The manufacturers of Great Britain have not only been making merchandise to supply the needs of the army and the government since the war began. They have also been going after foreign markets, and the Commercial Intelligence Branch of the British Board of Trade (an office corresponding to the Bureau of Foreign and Domestic Commerce in Washington) has given them the heartiest of co-operation. Sample exhibits, reports on definite trade opportunities, all sorts of confidential information concerning openings in foreign countries, have been provided by the Commercial Intelligence Branch to an extent previously unheard of in England. The fact that British exports have kept up to such a high level despite the loss of several very important consuming markets because of the war, has been in no small part due to the Government assistance which has been rendered the British trade.

Similarly, in the other European countries engaged in war, foreign trade promotion by the government has been a noticeable feature. In France, the National Office of Foreign Commerce has substantially increased its activities, encouragement has been given to French Chambers of Commerce abroad, and everything in the way of government trade promotion has taken on new life. There has been more active interest in foreign trade, that is, in the export trade in France during the past two years, than there ever was before. At this time there is in this country an important merchant from Paris representing a group of the biggest French manufacturers of fine textiles and wearing apparel. The French government has had a commission of its leading business men visit the United States to study trade opportunities and to make arrangements for increasing commerce between the United States and France during and after the war. In Paris, there has been held a so-called "Reconstruction Exposition." In Lyons, a determined effort has been made to develop the Lyons Fair to rival or even replace the Leipzig Fair.

Of course, industrial and commercial preparedness on the broadest lines has been the subject of the great Paris conference between representatives of England, Belgium, France and Russia, and other allied governments.

In a corresponding manner there has been held the Dresden conference of representatives of the Central Powers and their allies. This conference like the Paris conference had for its purpose the formulation of plans for industrial and commercial preparedness during and following the war.

Germany and Austria have both had substantial government organizations for promoting foreign commerce and while the export trade of these countries has languished somewhat during the war, interest in developing export trade after the war has not in the least diminished. The business men are working right with

the government to see that all possible preparation for intense commercial competition is made.

In Russia, Spain, Italy and Japan, likewise, all possible means for increasing and stimulating present and potential foreign trade are being availed of. Even some of the South American countries that we think of only as suppliers of raw materials and purchasers of manufactured commodities have been able to develop export business in other manufactured goods and are now preparing to extend their business in these commodities.

In the manufacturers and merchants of our country are going to hold the foreign business that they now have, and are going to keep up their end in the commercial competition that is bound to follow the war, it is absolutely necessary that our Government and our business men through their organizations, should leave no stones unturned to be thoroughly prepared. In addition to commercial and industrial preparedness on the part of the business men themselves, we should have the advantage of a better rounded-out service in the Bureau of Foreign and Domestic Commerce, which has done, and is now doing excellent work.

Methods of distribution in South America, Russia and China, involve a study of export and import houses; the position of the foreign manufacturer; different types of middlemen; and different retail agencies, including the department store, chain store, mail order house, and regular retailer.

The investigations into advertising in South America, Russia and the Far East, involve a study of different mediums, including trade papers, newspapers, and other periodicals, cards, billboards, window display and electric sign advertising, with careful attention to the customs and traits of the different peoples.

The handbooks on commercial and industrial conditions to be prepared for Japan and the Dutch East Indies, and Africa, should afford the American business man knowledge of fundamental conditions in these countries that he does not possess in convenient form at the present time.

It is interesting to note that among the investigations to be undertaken by the Bureau of Foreign and Domestic Commerce in the year 1917-18 is one into chemicals, dyes, paints and varnishes for South America.

An Improved Automatic Liquid Weighing Scale

The purpose of any liquid meter is to automatically measure and to record the amounts or quantities of liquids used. This can be done either by simultaneous determinations of the volume and density or by weighing. In determinations of quantities by the first method the density is usually disregarded. Liquid meters may then be divided into two main classes viz.: Volume type machines and weight type machines.

A machine belonging to the latter class is made by the John Simmons Co., 108 Center Street, New York City, and is known as the Leinert automatic gravity scale. Fig. 1 shows a photograph of this machine and Figs. 2 and 3 show sectional drawings. It is used for measuring by weighing such materials as water, oil, sugar juice, ammonia, brine and other liquids, and is not affected by the temperature.

Referring to Fig. 2, the apparatus consists of two measuring tanks of equal size A-1 and A-2, fitted each at one end with one or more siphon pipes C and at the other with weights D. The tanks work on the knife edges, "B," which are located at less distance from the counter weights D, than from the siphon pipes C. The liquid to be measured flows through the inlet pipe E,

passing along the deflector *F* into either tank, for instance as shown, in Fig. 2, into the left hand tank A-1. The weights *D* are so adjusted that the tanks will remain in a horizontal position until they contain a certain definite weight of liquid then they will tilt into the position shown by the dotted lines on Fig. 3, and the

FIG. 1—GENERAL VIEW OF SCALES

liquid will begin to flow through the siphon pipe *C*. After this flow has been started and the level of the liquid in the tank has fallen sufficiently, the tank tilts back again to its original position by the influence of the weights *D* the siphon continuing in action until the tank is emptied. As each tank assumes the position, indicated by the dotted lines Fig. 3, it suddenly tilts the deflector *F* over, so that the liquid, instead of continuing to flow into the tank A-1, begins to flow into the other tank A-2, when the same operation as already

FIG. 2—FRONT SECTIONAL VIEW

described is repeated and continued. It will thus be seen that both tanks are filled automatically with fresh liquid, while the measured liquid runs away into a reservoir, or other receptacle as required. As each tank tips the number of pounds contained is registered on the counter *G*, which is actuated by the deflector *F*.

When either tank is in a horizontal position the deflector *F* rests upon the support *J*, not touching the tanks, therefore the time of tipping and the accuracy cannot be affected, either by the weight of the deflector, or by the pressure of the running liquid in the deflector, or by the resistance in the mechanism of the counter.

In cases when the rate of flow varies considerably, the only source of inaccuracy is the varying quantities

of liquid, which falls into the tank during the time of the tank motion. To eliminate this error a Type B weigher has been devised, in which at the moment of tipping but a small flow feeds the tank, the larger part of the total flow being previously deflected into the other tank by means of a simple float mechanism.

FIG. 3—SIDE SECTIONAL VIEW

In the latest improved type the deflector has been replaced by a circular valve. The machines are made in various sizes, ranging in capacity from 600 lb. per hour to 120,000 lb. per hour for ordinary liquids. It is claimed that an average accuracy of 0.5 per cent can be maintained by the Type A and Type C machines and that the Type B machine will register with an accuracy of 0.4 per cent regardless of changes in temperature or specific gravity of the liquid.

Work of the Bureau of Mines

From the annual report of the Secretary of the Interior we cull the following notes on the work of the Bureau of Mines, omitting the introductory notes on the purpose and chief features of work of the bureau, decrease of accidents in coal mines, rescue and first-aid work, improvement of health conditions in mines, and prevention of coal-mine explosions.

Fuel investigations.—In its efforts to increase efficiency in the use of mineral fuels the bureau is studying the properties of these fuels and the methods of burning them in furnaces and gas producers. Also it is collecting, analyzing, and testing samples of coal purchased under specifications for Government use. In the fiscal year 1916 the aggregate cost of the coal represented by these samples was \$7,800,000. During the year the bureau continued to assist, in the capacity of a consulting fuel engineer, various departments and establishments of the Government in solving problems relating to the purchase of fuel and the efficient use of fuel for heating or power.

Problems of mineral technology.—The mineral technology investigations of the Bureau of Mines cover the minor metals, the rare and the precious metals, the metalloids and the nonmetals, brass and other nonferrous alloys, abrasives, cement, mineral products used as building materials, and many different minerals used in the arts.

In the United States 75,000 persons annually die of cancer, through the radium investigations of the bureau, in cooperation with the National Radium Institute, two great hospitals obtained during the year a

goodly supply of radium for the treatment of that disease. Low-grade radium-bearing ore, heretofore wasted, was concentrated successfully in a mill especially designed for the purpose. This concentrate, as well as high-grade carnotite ore, is being treated at the Bureau of Mines plant at Denver, which is now producing radium at the rate of 5 grams a year. The cost of production since operations began in June, 1914, has been less than \$40,000 a gram, as compared with a market price of \$100,000 to \$120,000 a gram. This radium is not sold, but is to be used in the treatment of cancer.

Incidental to the production of radium at the Denver plant many tons of iron vanadate that can be used in the manufacture of high-grade vanadium steel and many tons of uranium oxide, used in coloring glass and making tool steel, have been produced. For an expenditure of less than \$35,000 the Bureau of Mines will receive as its share of the results of the cooperative agreement at least \$100,000 worth of radium.

In normal times the metal losses in brass melting in the United States annually amount to \$3,000,000, and during the past year of high prices and large production have probably been nearer \$10,000,000. As a result of its investigations of these losses the Bureau of Mines has devised an improved electric melting furnace which will be thoroughly tested on a commercial scale during the coming year. Also, because of the excessive loss of metal, sometimes running as high as 40 per cent, in melting scrap aluminum, the bureau has investigated methods of melting aluminum chips and is publishing the results.

In its clay-industry investigations the bureau has studied methods of so treating the secondary kaolins found in almost unlimited quantities in the Coastal Plain region of Georgia and the Carolinas as to render them applicable to the production of white wares. The results have demonstrated that these kaolins can be cheaply purified and that the purified material is superior to the best English china clay for making china, white crockery ware, and white tile.

Increasing efficiency and lessening waste in the petroleum and natural-gas industries.—Through its petroleum division the Bureau of Mines is investigating problems of technology, engineering, and chemistry in the production and utilization of oil and gas. The petroleum-technology investigations deal chiefly with practicable methods of eliminating waste in drilling wells and of recovering a larger proportion of the oil or gas stored in the productive sands; the engineering-technology investigations deal with storage, the prevention of losses from fires, and the manufacture of gasoline from natural gas; and the chemical-technology investigations deal with the mechanical development of the Rittman process for manufacturing gasoline, toluene, and benzene, and the improvement of methods for analyzing and testing petroleum and petroleum products.

Operators in different fields have been shown the need of properly protecting oil and gas sands from infiltrating water and of sealing wells so as to confine the natural gas securely until such time as it is utilized. Also, the bureau demonstrated the advantages of using mud fluid in drilling wells. Operators in Kansas and in the Blackwell field of Oklahoma are successfully using methods the bureau advocates. In the Blackwell field the operators should recover at least 80 per cent of the gas in the gas sands, whereas in older fields the recovery has been less than 10 per cent. A conservative estimate of the value of the gas that will be saved through the use of approved methods in the Blackwell field is \$20,000,000.

The bureau is cooperating with the Bureau of Indian Affairs in the supervision of oil and gas operations on Indian lands.

Mechanical details of the Rittman process for making gasoline, benzene, and toluene were perfected during the year and the process was shown to be successful on a commercial scale. Tests have indicated how cheaply gasoline can be made from stove distillate.

Various gasolines sold in this country in 1915 were tested to determine their value as motor fuel. Other investigations included the production of gasoline from natural gas and the examination and analysis of petroleum.

Study of metallurgical problems.—In its metallurgical work the bureau continued to cooperate with the Selby and Anaconda smelter commissions, and during the year published as a bulletin the comprehensive report of the Selby Smelter Commission on alleged nuisance and damage occasioned by the Selby smelter in California. Especial attention is being given to the removal of sulphur from smelter gases. Cooperative work with the Anaconda Smelter Commission in the improvement of smoke conditions at the Anaconda smelter in Montana has led to the construction at the smelter of the first units of an electrical apparatus for treating smoke and to the operation of the first units of a sulphuric-acid plant that is to have a daily capacity of 140 tons of acid. Studies to effect the utilization of the acid in the manufacture of phosphates in Montana are in progress.

Under a cooperative agreement with the University of California the bureau has established a mining experiment station at Berkeley, Cal., where it is investigating problems relating to the smelting of lead and copper ores. Some of these problems are the absorption and purification of the sulphur dioxide in smelter smoke and the reduction of the gas to elemental sulphur by the wet Thiogen process. A study of the reduction of barium sulphate, a substance used in making paints and in various chemical industries, was completed.

Other work at Berkeley includes investigation of the improvement of the cyanide and other hydrometallurgical processes for treating ores of gold through the study of the efficiency of machines for crushing ores, the settling of slimes, and the behavior of aluminum in cyanide solutions.

Investigations at the Salt Lake City experiment station, conducted in cooperation with the University of Utah, deal chiefly with methods of preventing wastes in the concentration and metallurgical treatment of non-ferrous ores, especially ores of lead and zinc, with the purpose of making available as ore the great bodies of material now considered waste. Encouraging results have been obtained in the treatment of lead ores by a chloridizing roast and leaching with a solution of common salt, in a volatilization process for treating oxidized ores of zinc, and in investigations of the flotation process for concentrating ores.

An investigation of hazards at blast furnaces in Pennsylvania was made in cooperation with the Pennsylvania Department of Labor and Industry. The dangers peculiar to work about Bessemer converters and open-hearth furnaces at steel plants have been investigated, and an investigation, in cooperation with the Federal Public Health Service, of health conditions in the steel and metallurgical plants of the Pittsburgh district was completed.

Comprehensive studies of the corrosion of metals in mines, with especial reference to damage to mining equipment and the corrosion-resisting qualities of various metals were continued through the year.

Investigation of the fluidity of blast-furnace slags, one purpose of which is to furnish metallurgists and

furnacemen with reliable data for use in smelting lean and complex ores, is being continued, and the results are being published. A new high-temperature viscosimeter has been developed by which the viscosity of slags can be accurately measured to a temperature of 2900 deg. F., or about 900 deg. higher than the highest temperature previously used in viscosity measurements of any substance.

In cooperation with the State School of Mines of Missouri, the bureau is continuing a study of the milling of lead and zinc ores in the Joplin district, Missouri, with particular reference to milling losses and the possibilities of treating the ores by flotation.

Chemical researches.—In addition to the chemical investigations already mentioned, the bureau studied the composition and properties of mine gases and natural gas. The investigations included an absorption method of extracting gasoline from natural gas which, if generally applied, will make possible the recovery of 100,000,000 gal. of gasoline from natural gas each year; the errors that may arise in commercial methods of measuring natural gas at high pressure; the perfecting of a gas detector for use in mines and other places; methods of gas analysis; the chlorination of natural gas with a view to making tetrachloride, chloroform, and other valuable products; and the fusibility of coal ash as related to the formation of clinker in fuel beds.

Other investigations.—Special investigations that were described in reports published during the year or are still in progress include placer-mining methods, especially the use of gold dredges; iron-ore mining and iron making in the United States; utilization of low-grade fuel; gas-producer practice; and factors controlling the use and the market prices of fuel.

Personal

Mr. J. W. Beckman, consulting chemical engineer of the Great Western Power Co. and the Great Western Electrochemical Co. of San Francisco, Cal., and Mr. H. E. Linden, formerly associated with Stone & Webster, have formed the Beckman & Linden Engineering Corporation, with offices at 604 Balboa Building, San Francisco, and closely associated with it will be the Chemical Development Corporation. The object of this corporation will be primarily to develop uses and processes for the handling of many of the dormant resources available on the Pacific Coast.

Messrs. Frederick G. Cottrell and Dorsey A. Lyon of the United States Bureau of Mines were in Golden, Col., recently, conferring with R. B. Moore of the Colorado branch of the bureau and the authorities of the Colorado School of Mines relative to the co-operative investigations which are to be undertaken next year.

Mr. J. V. N. Dorr was recently a visitor in Denver in connection with business at the Denver office of the Dorr Company.

Mr. R. S. Foster has resigned his position as safety engineer at the Butte Mines of the Anaconda Copper Co. and has accepted a position with the Doe Run Lead Co. at Flat River, Mo., in a similar capacity.

Mr. Geo. C. Hicks, Jr., vice-president and engineer of the P. H. and F. M. Roots Co. of Connerville, Ind., for the past fifteen years, announces his retirement from the company on Jan. 1, 1917. Mr. Hicks will act as consulting engineer for the company for a short time. Before taking up work again he expects to take a six months' vacation.

Mr. R. H. Hodge, formerly foundry expert of the Western Foundry & Machine Co., is now superin-

tendent of the Ogden Iron Works, which is erecting a plant at Ogden, Utah. Mr. George J. Silver, formerly manager of the Western Foundry & Machine Co., will be consulting engineer.

Mr. Dyke V. Keedy, consulting and metallurgical engineer, of 6 Beacon Street, Boston, Mass., has gone to South America on professional business, to be gone some three months.

Mr. K. L. Kithill, head of the Arizona branch of the Bureau of Mines at Tucson, Ariz., has resigned his position with the government, and anticipates entering in business for himself at Denver.

Mr. L. O. Koven was the recipient on Dec. 21 of a sterling silver set consisting of six individual plates and tray, suitably inscribed, as a token of appreciation from the Eastern Supply Association, of which Mr. Koven was the president for the last three years.

Mr. A. R. Levin has been appointed New York manager for the Supplee-Biddle Hardware Company, Philadelphia, Pa., with offices at 30 Church Street.

Mr. I. L. Merrill, president of the Hedley Gold Mining Co., has left his home at Los Angeles, Cal., to inspect the company's properties at Hedley, B. C., Canada.

Mr. C. E. Mills has been elected as managing director for the Cananea Consolidated in Sonora, Mexico. Mr. Mills was the well known general manager of the Inspiration Consolidated, previous to the acceptance of his new position.

Mr. Robert Schubert, metallurgical engineer, sailed for Stavanger, Norway, on Dec. 28, to accept a position with the Stavanger Electro Staalwerk.

Mr. Francis P. Sinn of the New Jersey Zinc Co., Palmerton, Pa., has been elected a director of the National Safety Council. The council has a new section devoted to copper, lead and zinc smelting plants.

Mr. Stanley M. Tracy, until recently western district manager in the Chicago office of the Driver Harris Wire Co., is now assistant general sales manager at the main office and works of the company, Harrison, N. J.

Mr. F. H. A. Wielgolashi, a prominent engineer and nitrate expert from Norway, has recently come to Puget Sound in the interests of the American Nitrogen Products Company. He is now supervising the operation of the furnaces at the company's plant at La Grande, Wash., of which he is the inventor and will have direct charge of the plant for several months.

Mr. T. K. Wilkinson has returned to the Baltimore Copper Smelting & Rolling Company, Baltimore, Md., after an absence of two years.

CURRENT MARKET REPORTS

The Iron and Steel Market

The iron and steel market has continued dull by comparison with the intense activity that characterized the month of November. Strictly new buying has been light in both pig iron and finished steel, and there has been some decrease in specifications filed against finished steel contracts. Before the holidays the disposition to "go slow" was attributed almost exclusively to the suggestion that peace terms might be arranged for the European belligerents but the more mature reflection of the trade has led to the conclusion that nothing occurred that might not have been expected at almost any time. There was no occasion to assume that the war would never end, or to assume the impossible, that no peace overture would be made without several months' advance notice being given. The disposition now is to give more weight to the idea that the excited buying movement had to end soon by exhausting its force, and

the double influence of the peace overture and the holidays chanced to stop it rather suddenly.

There is no decrease whatever in the demand for material. It is simply in the making of additional engagements that a slowing down has occurred. Buyers are exerting as much pressure as ever upon mills to expedite their deliveries, and perhaps even more, as the partial breakdown of the transportation system of the country, under an unprecedented load, has slightly curtailed deliveries and occasioned fears that there would be a still more serious interruption to traffic.

It is only because the weather has been unseasonably mild that transportation has been maintained so well. A really cold snap would probably make more serious trouble than has yet been experienced. At Christmas time between twenty-five and thirty-five blast furnaces were banked on account of not receiving coke, chiefly from the Connellsville region, and many others were forced to slow down a trifle. At this writing nearly all the banked furnaces have resumed, partly on account of coke accumulating, but pig iron production is still distinctly less than the physical capacity. During the holidays there were considerable accumulations of finished steel at various works, partly by reason of car shortages and partly on account of embargoes. There have been frequent changes of rolling schedules on account of embargoes, and even those changes tend to cut down. At the moment very little steel is accumulating at mills but no progress to speak of has been made toward moving steel already accumulated. The industry is booked for serious times in the next two months and is much more concerned with production and transportation problems than with market problems.

PIG IRON

The pig iron market has been practically stationary as to prices. There is scarcely any inquiry for deliveries in the second half of the year, while there is a fair run of inquiry for earlier deliveries, ranging from spot to first half. In foundry and malleable grades premiums for quick delivery of small lots are usually obtained. Basic iron may be a shade easier than thirty days ago for second half delivery, but is correspondingly stiffer for early deliveries. There is an excellent run of export demand, but the governing factor is the vessel situation. If there were more vessel room much more export iron could be sold. Bessemer iron is quotable at \$35 and basic iron at \$30, f.o.b. valley furnaces.

UNFINISHED STEEL

There is an almost complete absence of offerings of unfinished steel in any form. Brokers and merchants are constantly scouring the trade but only occasionally find an odd lot. The mills do not quote for forward delivery at all. For soft steel in the form of billets, blooms, slabs, sheet bars, etc., export bids are generally at least \$60, Pittsburgh or Youngstown, and sometimes run a little above that figure. Soft steel rods have brought \$75.

FINISHED STEEL

Prices of finished steel are practically stationary. Last advances were \$2 a ton in bars, plates and shapes, Dec. 20, as already reported, and \$4 a ton in wrought iron and steel pipe, Dec. 30. There is no expectation of further changes in steel prices for some time to come, or until distinctly new developments occur. There is no basis upon which prices could well be advanced, for delivery at mill convenience, as there is not much inquiry for the late deliveries, and the turnover in prompt material is so light that no very definite market is established at any time. There is certainly nothing in pros-

pect that would tend to depress prices, for the mills are more than comfortably filled with business for months and there is no incentive for any seller to cut prices.

Naturally, there is speculation as to what would occur were definite steps undertaken for the establishment of peace. By far the major part of the business on books of steel mills is for domestic consumption, of a character that would continue, peace or war. Buyers would expect an eventual readjustment in prices, but in the great majority of cases would not be in position to await the readjustment. While the view certainly has not been generally expressed, there is reason to doubt whether a continuance of the war, say for two years more, might not seriously decrease the demand for steel. The shipping situation is such that exports cannot be increased and the extremely high prices now current should tend eventually to alter the balance between domestic demand and production, seeing that production is increasing steadily except as interfered with by transportation conditions. It is more generally believed than formerly that the peace demand for steel, once prices have been readjusted, will be very large.

Non-Ferrous Metal Market

Monday, Jan. 8.—The markets in all the metals continue dull and both buyers and sellers have been holding off awaiting future developments. The statistics show 1916 to have been a most remarkable year both in production and value of product. Copper shows signs of developing some weakness, but this may only be temporary. Lead is strong and tin is steady. Spelter is unchanged in a dull market.

Copper.—Business in copper continues dull and consumers continue to be sellers along with producers and dealers. A feature of the market is the little interest shown in futures beyond March. Prices have declined for prompt delivery from 31.50 cents asked for both electrolytic and Lake on Dec. 23 to 28.25 cents for electrolytic and 29.00 cents for Lake on Jan. 5. The large producers are holding off and are holding their quotations on third and fourth quarter deliveries at 6.00 to 7.00 cents above the outside market. February delivery is quoted at 28.50 for Lake and 27.75 for electrolytic. First quarter electrolytic is held at 27.75, second quarter at 26.00 to 27.00, third quarter at 25.00 to 26.00, and fourth quarter at 24.00 to 25.00 in the outside market.

The copper statistics issued by the Geological Survey show an increase of 540,000,000 lbs. in smelter production in 1916 and an increase of 677,000,000 lbs. in refinery production. The refinery production is given as 2,311,000,000 lbs., and the smelter production as 1,928,000,000 lbs. The exports as given by the American Metal Market Report were 760,000,000 lbs., leaving 1,633,429,666 lbs. available for home consumption. How much of this was actually used is not known. A large demand for copper is expected from Germany after the war and Canada will probably want considerable shortly in view of her large munitions contracts, but whether domestic consumption will be large enough to take care of the balance not exported in 1917 will be a feature which will be watched with interest, as refinery capacity is being still further increased.

Tin.—The market has shown an improvement and on Jan. 1 Straits had advanced £3 10s. to £182 5s., with a similar advance in Standard. Our price for prompt delivery Straits jumped to 43.00 cents on Jan. 2, but has since eased off to 42.50 on little interest being shown by buyers. Deliveries in December, 1916, were 4082 tons, which are below normal. The total visible supply, including stocks afloat and on hand in all countries on Dec. 31 was 20,737 tons, or over 4000 tons

more than at the same time last year. The stocks in the United States were 3511 tons.

Lead.—Lead is unchanged and the market has continued dull but firm. The trust price is still on the basis of 7.50 cents New York with the outside price 7.50 to 7.62½. The production in 1916 was a new record of 579,600 tons. Exports are estimated at 108,200 short-tons lead produced from domestic ore, a gain of 21,000 tons over 1915. The domestic demand is large and partly explains the small amount for sale.

Spelter.—Spelter has remained quiet and practically unchanged, at 9.67½ to 9.92½ New York for prompt shipment. Futures are slightly lower on account of the small demand. February is quoted at 9.55 to 9.80, March at 9.42½ to 9.67½, and second quarter at 8.92½ to 9.17½. The production in 1916 was 658,000 tons, or an increase of 34 per cent over 1915. Exports were 210,500 tons, or an increase of 59 per cent. Domestic consumption increased 22 per cent. The low prices prevailing at present are the result of production overtaking the demand.

Other Metals.—Antimony is unchanged at 14.25 to 14.50. Aluminum is unchanged at 60.00 to 64.00 cents for the No. 1 Virgin metal. Magnesium is unchanged at \$3.50 per lb. Electrolytic nickel is 50.00 cents per pound; Cadmium \$1.50; Cobalt \$1.50 and quicksilver \$90.00 per flask; tungsten ore is \$17.50 to \$20.00 per unit and silver 75½ cents.

Chemical Market

There has been a decided lull in practically all branches of the chemical trade during the past fortnight. The holidays interfered with prompt and nearby business to a marked degree and as a result of the peace negotiations, contracts have been invariably held up. Heavy chemicals that have been slowly but steadily advancing the past two or three months recorded marked declines at the first announcement of the possibility of peace and have not recovered. There is a probability that higher prices will be reached for deliveries in nearby positions with contract business holding fire until the peace question is definitely decided.

As a result of this condition and the likelihood of munition contracts halting, glycerin has been subject to a rather sharp decline. For C. P. and dynamite business has passed as low as 53c, although the general asking price is 1c. to 2c. higher. The C. P. and dynamite grades are quoted on about the same level at the moment.

Potassium cyanide is now practically off the local market. The sodium and the mixture are being traded in to some extent with the former quoted at about \$1.75 to \$1.85 spot and the mixture at \$2.05. Future shipments from Japan are offered at lower figure, sodium cyanide for example, at \$1.20. But small amounts of Japanese material are en route so that the spot market is not affected.

Soda ash, caustic soda, bichromates of soda and potash and bleaching powder have not recovered from the decline recorded coincident with the announcement of peace negotiations and contract business has been almost entirely suspended.

Despite an enormous production, sulphuric acid is selling at a somewhat higher level. Important Pennsylvania producers are asking \$30 for 66 degree brimstone f.o.b. Some business of this description has passed at \$28 however. The production of acid in the United States last year was enormous. In the absence of positive figures it is possible to arrive at a fairly accurate estimate. The imports of pyrites totaled 1,500,000 tons. The total consumption was possibly 2,300,000 tons. On the basis of 50 per cent sulphur con-

tent of this ore and a theoretical recovery of 2.35 tons of acid from each ton of pyrites consumed, the production of pyrites acid would have been approximately 5,400,000 tons of 50 deg. Baume acid. This figure does not include the acid production from brimstone, statistics of which are not available. The brimstone acid production in 1916 was the heaviest on record. The actual production of both brimstone and pyrites acids in 1915 was 3,868,152 tons.

Other mineral acids have not been subject to much change. Nitric acid, so important with munition manufacturers, has remained stationary, but the feeling was an easier one. Muratic acid business continues spasmodic.

In the coal tar classification, there have been freer offerings of aniline oil, dinitrophenol and phenol. The aniline oil market appears to be suffering more from keen competition than from an over-production, as there are hardly more than fifteen active producers at the moment. As a result of new manufacturers entering the field, offerings of dinitrophenol are more abundant and prices are easier. As a result of a refusal of one large consumer to accept contract deliveries, surplus stocks reached the open market and prices were easier. This condition is temporary, however. Most phenol producers are well sold out.

Benzol is somewhat firmer. The leading producers have advanced prices somewhat. The production is well covered by contract. Toluol for delivery next year is particularly scarce and large manufacturers advise that the only stocks that will be available will be surplus stocks over their contracts.

Alcohol business has been quite large and the market has held up well in view of the heavy business. Production is proceeding upon a record scale.

Arsenic has advanced with stocks light. All producers have marked up selling prices. This is, perhaps, incidental to the season as manufacturers of paris green and spraying solutions are preparing for an active spring season.

Sulphate of copper has been subject to practically no change during the fortnight. Firmness expected has not materialized as the export business absorbed a great bulk of this production and the peace negotiations have, of course, suspended important business for foreign account.

Sulphate of ammonia, except for resale lots, is practically out of the market. Producers are sold, as a rule, six months ahead. The 1916 production of ammonia reduced to the sulphate equivalent is figured as 325,000 tons, an increase of 113,000 tons over 1915.

General Chemicals

WHOLESALE PRICES IN NEW YORK MARKET JANUARY 8, 1917

Acetone, Drums	100 lb.	2.24	21
Acid, acetic, 28 per cent	100 lb.	3.75	7.75
Acetic, 56 per cent	100 lb.	8.00	8.25
Acetic, glacial, 99½ per cent, carboys	lb.	.32	.35
Boric, crystals	lb.	.13	.13½
Citric, crystals	lb.	.01½	.06
Hydrochloric, commercial, 18 deg.	lb.	.01½	.013½
Hydrochloric, 20 deg	lb.	.02	.02
Hydrochloric, C. P., conc., 22 deg	lb.	.02	.02½
Hydrochloric, 30 per cent, in barrels	lb.	.01½	.05½
Lactic, 44 per cent, light	lb.	.13½	.14½
Lactic, 22 per cent	lb.	.06½	.07
Nitric, 36 deg	lb.	.04½	.05
Nitric, 42 deg	lb.	.05½	.06
Oxalic, crystals	lb.	.44	.45
Phosphoric, 55 per cent	lb.	.30	.32
Picric	lb.	.60	.75
Pyrogallol, resublimed	lb.	3.10	3.25
Sulphuric, 60 deg	ton	20.00	21.00
Sulphuric, 66 deg	ton	27.00	30.00
Sulphuric, oleum (Fuming), tank cars	ton	35.00	40.00
Tannic, U. S. P. bulk	lb.	.88	.92
Tartaric, crystals	lb.	.66	.67
Alcohol, grain, 188 proof	gal.	2.68	2.70
Alcohol, Wood, 95 per cent	gal.	.88	.90
Alcohol, Dehydrated, 180 proof	gal.	.65	.66
Alum, ammonia lump	lb.	.04	.04½
Alum, chrome	lb.	.21	.22
Alum, potash lump	lb.	.65	.66

Intermediates, Etc.

Aluminum sulphate, technical	lb.	.017	.024	Alpha naphthyl am ne.	lb.	1.00	1.25
Aluminum sulphate, iron re.	lb.	.034	.041	Aniline oil	lb.	.214	.224
Ammonia aqua, 26 deg. carbons	lb.	.054	.054	Aniline salts	lb.	.28	.30
Ammonia, anhydrous	lb.	.124	.13	Anthracene, 80 per cent.	lb.	.175	.500
Ammonium carbonate	lb.	.134	.14	Benzaldehyde	lb.	1.80	1.90
Ammonium nitrate	lb.	.014	.014	Benzidine Base	lb.	1.50	1.65
Amyl acetate	gal.	4.25	4.50	Benzidine, Sulphate	lb.	8.50	9.00
Arsenic, white	lb.	.084	.094	Benzoic acid	lb.	.90	.95
Arsenic, red	lb.	.65	.70	Beta naphthol Sublimed	lb.	—	—
Barium chloride	ton	90.00	95.00	Dierbol benzol	lb.	—	—
Barium sulphate (Blanc Fixe) powder	lb.	.01	.012	Dimethylamine	lb.	.55	.57
Barium nitrate	lb.	.11	.12	Diphenylamine	lb.	2.15	2.25
Barium peroxide	lb.	.40	.50	H acid	lb.	1.50	1.75
Bleaching powder, 35 per cent	lb.	.0115	.0120	Metaphenylene diamine	lb.	.60	.62
Borax, crystals, sacks	lb.	.074	.08	Monochlorobenzal	lb.	.30	.32
Bromine, etials	ton	28.00	29.00	Naphthalene Flake	lb.	2.00	2.10
Bromine, technical	lb.	1.20	1.30	Naphthalene acid, crude	lb.	1.00	1.05
Calcium acetate, crude	lb.	.034	.034	Ortho-aminophenol	lb.	1.50	1.60
Calcium carbide	ton	68.00	75.00	Ortho-toluidine	lb.	4.50	6.00
Calcium chloride, 70-75 per cent, fused, lump	ton	21.50	22.00	Paranitrophenol	lb.	1.60	1.75
Calcium peroxide	lb.	—	—	Paraphenylenediamine	lb.	3.50	3.75
Calcium sulphate	lb.	—	—	Para-toluidine	lb.	2.00	2.10
Carbon phosphide	lb.	—	—	Resorcin, technical	lb.	.51	.53
Carbon bisulphide	lb.	.054	.06	Resorcin, pure	lb.	8.75	9.50
Carbon tetrachloride, drums	lb.	.114	.16	Salicylic acid	lb.	20.00	22.00
Caustic potash, 88-92 per cent	lb.	.81	.86	Sulol	lb.	2.25	2.30
Caustic soda, 70 per cent	lb.	.014	.014	Sulphanilic acid	lb.	.40	.45
Chlorine, liquid	lb.	.14	.20	Toluidine-mixture	lb.	1.00	1.10
Coppers	100 lb.	1.10	1.25				
Copper carbonate	lb.	.70	.37				
Copper cyanide	lb.	.124	.124				
Copper sulphate 99 per cent large crystals	lb.	.38	.40				
Cream of tartar, crystals	100 lb.	1.634	1.80				
Epsom salt, bags	lb.	.114	.12				
Formaldehyde, 40 per cent	100 lb.	.75	.80				
Glauber's salt	lb.	.53	.54				
Glycerine, bulk c. p.	lb.	.60	12.00				
Hydrogen peroxide, gross	lb.	4.00	4.25				
Iodine, resublimed	lb.	.024	.10				
Iron oxide	lb.	.034	.014				
Iron sulphate	lb.	.13	.134				
Lead acetate, white crystals	lb.	.084	.084				
Lead arsenate	lb.	.154	.16				
Lead nitrate	lb.	.084	.09				
Litharge, American	lb.	1.00	1.05				
Lithium carbonate	lb.	.66	.70				
Manganese dioxide	lb.	.124	.15				
Magnesium carbonate, tech	lb.	.14	.14				
Nickel salt, single	lb.	.114	.114				
Nickel salt, double	lb.	1.00	1.10				
Phosphorus, red	lb.	.85	.90				
Phosphorus, yellow	lb.	.40	.41				
Potassium bichromate	lb.	1.30	.34				
Potassium bromate, granular	lb.	.34	.36				
Potassium carbonate calcined, 80-85 per cent	lb.	.64	.65				
Potassium chlorate, crystals	lb.	2.15	2.50				
Potassium cyanide, 98-99 per cent	lb.	3.15	3.50				
Potassium iodide	ton	435.00	450.00				
Potassium muriate, 80-85 p. c., basis of 80 p. c.	lb.	.27	.30				
Potassium nitrate	lb.	2.65	3.00				
Potassium permanganate	lb.	.91	.93				
Potassium prussiate, red	ton	263.00	275.00				
Potassium prussiate, yellow	lb.	.33	.34				
Potassium sulphate, 90-95 p. c., basis 90 p. c.	lb.	.14	.14				
Rochelle salts	lb.	.174	.18				
Salt ammonia, gray, gran	100 lb.	1.00	1.10				
Salt ammonia, white, gran	lb.	.70	.75				
Salt soda	lb.	.464	.464				
Salt cake	lb.	.0290	.0295				
Silver cyanide	lb.	.0340	.0350				
Silver nitrate	oz.	.12	.13				
Soda ash, 58 per cent, light, flut	lb.	8.00	8.50				
Soda ash, 58 per cent, dense, flut	lb.	1.60	1.70				
Sodium acetate	lb.	.17	.174				
Sodium bicarbonate	lb.	.05	.054				
Sodium bisulphate, powd.	lb.	.25	.26				
Sodium chloride	lb.	1.80	1.90				
Sodium fluoride, commercial	lb.	.014	.014				
Sodium hyposulphite	100 lb.	3.274	3.324				
Sodium nitrate, refined	lb.	3.25	3.30				
Sodium nitrite	lb.	1.10	1.20				
Sodium peroxide	lb.	.014	.05				
Sodium phosphate	lb.	.31	.32				
Sodium prussiate yellow	100 lb.	.80	.80				
Sodium silicate, liquid	lb.	.024	.024				
Sodium sulphide, 30 per cent crystals	lb.	.12	.124				
Sodium sulphite	lb.	.44	.50				
Strontium nitrate	lb.	.394	.40

INDUSTRIAL

Financial, Construction and Manufacturers' News

Financial

Alliance Brass Foundry Co., Detroit, Mich., has been incorporated with a capital of \$50,000 to deal in machines. Incorporators are A. Manche, E. M. Sloman, D. W. Berry.

Alumite Corporation, Wilmington, Del., has been incorporated with a capital of \$20,000 to mine gold and silver.

American Explosives Co., St. Louis, Mo., has been incorporated with a capital of \$50,000. Incorporators are E. B. McAbee, E. Cole and J. H. Robb. Manufacture of deal in explosives.

American Fuel Company, Atlantic City, N. J., has been incorporated with a capital of \$500,000.

American Magnesium Corp., Niagara Falls, N. Y., has been incorporated with a capital of \$300,000 to manufacture and deal in magnesium, calcium, metals, coal, coke, etc. Incorporators are J. J. Devereaux, L. J. Hallenbeck, E. W. Burdick, 445 West 153d Street, New York.

Armour & Co., the Chicago packers, has purchased four of the largest tanneries in the Punksutawney, Pa., district, viz., The Big Run Tannery, the Gleasontown Tannery, the Driftwood Tannery, and the Merdix Run Tannery. The amount involved is believed to be about \$1,000,000.

Aroostook Pulp & Paper Co., Inc., Boston, Mass., has been incorporated with a capital of \$500,000. Incorporators are A. B. Flaming, G. S. Lewis, S. F. Johnson, H. Ketchum, E. T. Connolly, E. P. Lindsay.

Atlantic Potash Co., Eddyville, N. Y., has been incorporated with a capital of \$177,500 to deal in chemicals. Incorporators are S. E. Howard, S. A. Anderson, A. W. Britton, 65 Cedar Street, New York.

Bardeen Paper Co., Otsego, Mich., has increased its capital from \$175,000 to \$1,000,000.

The Benzol Products Company has increased its capital from \$1,000,000 to \$1,500,000.

Bowditch Dye Works, Inc., Boston, Mass., has been incorporated with a capital of \$10,000 to deal in cotton, wool, rays, dyes, etc. Incorporators are G. A. Vaughn, Dexter Elliott, E. Linesey, Jr., F. Ashton.

Bridgeport Iron & Metal Co., Bridgeport, Conn., has been incorporated with a capital of \$50,000. Incorporators are W. Alderman, Ansonia; P. Nowitz, Bridgeport; A. Alderman, Ansonia.

Bristol Power, Pulp & Paper Co. has been incorporated in Delaware with a capital of \$1,000,000 to deal in wood, paper, etc. Incorporators are M. Dougherty, M. C. Donohue, F. Giles, all of Wilmington.

Burd-Beidler Metals Corp., New York, has been incorporated with a capital of \$1,500,000 to manufacture hardware, mechanical appliances, jewelry and novelties. Incorporators are L. Burd, W. A. Leonard and J. F. Lynch, of New York City.

Burdett Gas Service Corporation, Wilmington, Del., has been incorporated with a capital of \$3,000,000 to manufacture gas oxygen and any article in which gas is used.

California Fiber & Pulp Co., Los Angeles, Cal., has been incorporated with a capital of \$50,000. Incorporators are A. J. Hime, E. C. Stegall, E. W. Bothwick, R. B. Turnbull, J. B. Meikle.

The Carbon Block Mining Co., Cincinnati, Ohio, has been incorporated with a capital of \$25,000. Incorporators, G. Rapp, and others.

The Carso Paper Co., Dansville, N. Y., has been incorporated with a capital of \$100,000. Incorporators are J. R. Carter, J. A. Ault, H. T. Kechev, L. C. Anderson, W. R. Carter, E. A. Carter.

Carson Hill Consolidated Gold Mines, Portland, Me., has been incorporated with a capital of \$300,000 to mine, mill, smelt and prepare all kinds of metals and ores, etc., for market.

Cayuga Tool Steel Co., Auburn, N. Y., has been incorporated with a capital of \$300,000 to manufacture furnaces, mills, iron and steel. Incorporators are J. B. King, J. H. Richards, H. D. Canaday, 2114 Canto. Avenue, Brooklyn, N. Y.

Central Cressosting Co., Winnetka, Ill., has been incorporated with a capital of \$200,000 to engage in general cressosting business. Incorporators are P. Kimmier, R. Swanson, E. S. Burling, H. Wood.

The Central Sugar Corp., Albany, N. Y., has been incorporated with a capital of \$3,400,000 to conduct a sugar plantation refinery and raise sugar. Incorporators are H. P. Dubois, F. S. Connett, F. J. Bomm, of New York City.

Chemical Pigment Co., Baltimore, Md., has been incorporated with a capital of \$255,000 to manufacture pigment and chemical products.

Chemical Products Corp., Camden, N. J., has been incorporated with a capital of \$200,000 to deal in chemicals. Incorporators are F. R. Hansell, J. A. MacPeak, I. C. Clow.

The C. H. Clark Oil Co., Cleveland, Ohio, has been incorporated with a capital of \$20,000 to deal in paints. Incorporators are I. T. Quick, J. M. Cantillon, C. H. Clark, I. M. Clark, A. R. Lawrence.

The Cleveland Foundry Co., the Cleveland Metal Products Co., and the Cleveland Factory Co. have announced to stockholders a plan of consolidation into a \$10,000,000 Metal Products Co. The Cleveland Foundry Co. produces oil stoves, the Cleveland Metal Products Co. sheet aluminum and holding concerns, and the other company is a realty concern.

Commercial Acid Co., E. St. Louis, Mo., has been incorporated with a capital of \$150,000. The company was organized by W. H. Cocke, J. W. Garbard and G. M. Byrns to manufacture and sell chemicals.

Concord Mining Co., Webb City, Mo., has been incorporated with a capital of \$100,000 to conduct a general mining business. Incorporators are C. E. Crane, F. S. Gardiner, F. Gray.

Consumers Explosives Co., Augusta, Me., has been incorporated with a capital of \$750,000 to manufacture explosives. Incorporators are E. M. Leavitt, E. L. McLean.

The Dellerbrook Chemical Co., Lima, Ohio, has been incorporated with a capital of \$50,000. Incorporator, E. R. Dellerbrook.

Dento Chemical Co., Dover, Del., has been incorporated with a capital of \$500,000 to carry on the business of chemists and druggists.

The Detroit Copper & Brass Rolling Mills, Detroit, Mich., has been incorporated with a capital of \$3,000,000.

Duall Leather Corp., New York, has been incorporated with a capital of \$630,000 to manufacture and deal in leather, textile fabrics. Incorporators are C. G. Quinn, C. A. Meier, W. McCarroll, 152 Broadway.

The Federal Dyestuff and Chemical Corporation, Kingsport, Tenn., has increased its capital from \$1,500,000 to \$2,000,000.

Goodwater Granite Co., Inc., Philadelphia, Pa., has been incorporated with a capital of \$550,000 to manufacture granite, iron and steel. Incorporators are W. L. Shumate, Jr., Birmingham, Ala.; Eugene Argen, and T. D. Ephes, Goodwater, Ala.

The Grand Rapids Grinding Co., Grand Rapids, Mich., has been incorporated with a capital of \$25,000 for manufacturing and selling machinery and metal goods. Incorporators are S. Owen, Livingston C. P. Hext, J. DeKoning.

Hattlesburg Pulp & Board Co., Portland, Me., has been incorporated with a capital of \$1,250,000 to manufacture pulp and paper.

Holland Aniline Co., Holland, Mich., has been incorporated with a capital of \$250,000 to manufacture and deal in aniline dyes. Incorporators are Frans Franklin and V. C. Maize, of Holland, and L. Weisberg, of Chicago.

Wood Foundry Co., Wilmington, Del., has been incorporated with a capital of \$50,000 to manufacture iron castings, steel castings, etc.

Ideal Piece Goods Dyeing Co., Paterson, N. J., has been incorporated with a capital of \$100,000 to operate factory for dyeing

dress goods and textile fabrics. Incorporators are C. M. Riva, J. D. Huyvetters, J. Davison.

Imperial Dye Wood Co., Inc., Hackensack, N. J., has been incorporated with a capital of \$125,000 to deal in dyewoods. Incorporators are A. C. Hart, A. A. Hart, Hackensack; J. S. Baker, Garfield.

Independent Mines Smelting Co., Inc., Wilmington, Del., has been incorporated with a capital of \$1,500,000 to operate the Ward-Abel Parabola Oil Burning Smelter and other devices.

The Lima Metals Foundry Co., Lima, Pa., has been incorporated with a capital of \$15,000. Incorporators are M. G. Bush, S. Wiesenthal, John Thomas.

The Loomis-Sielaff Co., Cleveland, Ohio, has been incorporated with a capital of \$150,000 to manufacture and deal in metal products. Incorporators are J. G. Fose, M. M. Feidner, H. E. Davis, W. G. Radcliffe, R. E. Kouba.

McKesson & Robbins, Inc., Milbrook, N. Y., has been incorporated with a capital of \$200,000 to manufacture and deal in chemicals, etc. Incorporators are C. and J. McKesson, H. D. Robbins, 91 Fulton Street, New York.

Midland Carbon Co., Wilmington, Del., has been incorporated with a capital of \$500,000 to deal in carbon black products.

Henry-Miller Foundry Company, Cleveland, Ohio, has been incorporated with a capital of \$1,000,000. Incorporator, T. E. Henry.

Montague Gold Mining Co., New York, has been incorporated with a capital of \$1,000,000 to engage in mining of gold, silver, lead, copper and other ores. Incorporators are F. E. Reese, T. J. Buckley, J. Lecour, Jr., all of New York.

Moore Paper Mill Corp., Buffalo, N. Y., has been incorporated with a capital of \$50,000 to manufacture paper and box board. Incorporators are W. P. Goodenough, B. S. and C. G. Moore, 207 Anderson Place, Buffalo.

The National Process Co., Cleveland, Ohio, has been incorporated with a capital of \$10,000 to deal in paints. Incorporators are C. Taussig, H. K. Fox, E. H. Blywise, A. M. Wilber and M. Skala.

Neosho Zinc Co., New Haven, Conn., has been incorporated with a capital of \$150,000. Incorporators are A. M. Brown, W. A. Wright, G. M. Elger.

The Northwestern Leather Co., Boston, Mass., has been incorporated with a capital of \$1,500,000.

Odorless Fertilizer Mfg. Co., Wilmington, Del., has been incorporated with a capital of \$250,000 to manufacture fertilizers.

O-Zel-O Company, Fort Wayne, Ind., has been incorporated with a capital of \$15,000 to manufacture chemicals. Incorporators are J. Miller, H. W. Muller, H. C. Barnes.

The Pennsylvania Rubber Co., Jeannette, Pa., has been incorporated with a capital of \$2,000,000.

Rosslyn Steel & Cement Co., Washington, D. C., has been incorporated with a capital of \$15,000. Incorporators are C. T. Kingsbury, C. E. Dale, W. T. Galliber, B. C. Downey, F. L. Wagner, A. A. Hoehling.

Rubber Patchit Corp., Manhattan, has been incorporated with a capital of \$80,000 to manufacture rubber and leather products and vulcanizing materials. Incorporators are F. Rogers, E. Goldfarb, C. Bogardus, 140 Nassau Street, New York City.

Seneca Copper Corp., New York, has been incorporated with a capital of \$1,000,000 to mine, mill and smelt gold, silver, copper, lead, etc. Incorporators are K. A. Duffy, S. Kramer, F. G. Fischer, 15 Broad Street.

The Shaeffer Oil Corporation, Wilmington, Del., is incorporated with a capital of \$50,000.

Sivalls & Brysons, Inc., Portland, Me., has been incorporated with a capital of \$800,000 to manufacture and deal in oil tanks, water tanks, and gas tanks, to acquire oil and gas lands, etc.

South American Electric Smelting Co., New York, has been incorporated with a capital of \$50,000. Incorporators are J. B. Pruyn, C. W. Whittlesey, W. P. Martin, 17 Battery Place.

South Florida Sugar Co., Miami, Fla., has been incorporated with a capital of \$50,000 to refine sugar.

Southern Oil Co., Bettyville, N. Y., has been incorporated with a capital of \$30,000. Incorporators are C. Beach, R. G. Porter, W. Porter, L. Thomas, T. Blakey.

The Stanley Aniline Chemical Works, of Lockhaven, Pa., has increased its capital stock from \$1,000,000 to \$2,000,000.

Superior Steel Corporation, Richmond, Va., has been incorporated with a capital of \$17,000,000. Incorporators are M. Rogers, president, W. J. Smelser, treasurer, A. J. Christman, secretary.

Thunderbolt Copper Co. has been incorporated in Delaware with a capital of \$2,000,000 to conduct a general mining business. Incorporators are C. A. Cole, Hackensack, N. J.; Robert A. Van Voorhis, Jersey City; A. R. Oakley, Pearl River, N. Y.

Universal Leather Co., Trenton, N. J., has been incorporated with a capital of \$50,000 to manufacture leather goods. Incorporators are W. E. Gips, S. P. Friedman, New York; C. K. Kuttner, M. E. Ruback, Newark.

Utah-Idaho Sugar Co., Salt Lake City, Utah, has been incorporated with a capital of \$10,000,000. Incorporators are Joseph Smith and Horace G. Whitney.

Utilities Co., Inc., Ringling, Okla., has been incorporated with a capital of \$1,000,000 that is to establish natural gas and electric plants and develop water power sites in southern Oklahoma. Incorporators are P. C. Ekern, C. Dings, W. D. Potter.

The Whitfield Iron Co., Cleveland, Ohio, has been incorporated with a capital of \$10,000. Incorporators are F. S. McGowan, A. R. Manning, Jr., S. Chestnut, J. M. Harris, J. K. Lee.

Construction and Operation

Arizona

JEROME.—The United Verde Extension plant, the erection of a new smelter on the C. V. Honkins branch, near Cottonwood, A. G. McGregor, well known metallurgist, will superintend the construction. He recently visited Jerome with President James S. Douglas of the Extension Company to investigate the possibilities, and it is understood that work will be pushed as fast as possible on the new plant.

TUCSON.—Reported Mineral Hill Mining Co. plans erecting smelter and concentrator plant. Frederick Minard, engr., 111 Broadway, New York City.

California

LOS ANGELES.—The C. W. Hill Chemical Company has purchased a large site on San Pedro Street, between Sixth and Seventh Streets, on which a new plant will be erected.

MANTECA.—The contract has been awarded by the Spreckles Sugar Company to the Dyers Construction Company, of Cincinnati, Ohio, for the \$2,000,000 sugar plant which will be erect at Manteca. The same construction company is building a \$1,000,000 refinery for the Whitehall estates near Tracy.

NEWPORT.—It is expected that the Newport Glass Company, Inc., will shortly operate its factory here, as machinery and equipment are being installed.

OAKLAND.—The East Bay Foundry will erect a \$50,000 plant at Thirty-second and Chestnut Streets. The company will manufacture cast iron to be used in ship building.

RIVERSIDE.—The Sterns-Roger Manufacturing Company of Denver, which has established several sugar mills in Colorado and Idaho, is erecting a \$10,000,000 million-dollar plant in Riverside if 10,000 acres of lands can be signed up. The Riverside and Arlington Chambers of Commerce are working for the plant.

SAN FRANCISCO.—The National Carbon Company has applied for a permit to erect a four-story and basement brick mill and factory building at the northeast corner of Brannan and Eighth Streets, which will cost \$220,000.

SAN FRANCISCO.—The Pacific Tank & Pipe Company announces the completion of the first of the buildings of its new plant located on a 95-acre tract near the Melrose Station of the Southern Pacific in San Francisco Bay. The plant at present comprises four main buildings from 200 to 300 ft. long and 160 ft. wide. The main office of the company is at 316 Market Street, San Francisco. The officers of the company are E. C. Pitcher, president and general manager; R. Streets, vice-president; George W. Gerkins, chief engineer, and F. W. Schmitz, sales manager.

SAN FRANCISCO.—Plans were considered for the construction and operation of a co-operative paper mill at the meeting of The California Press Association in De-

cember. It was pointed out that at \$7 a hundred for newsprint in ton lots and \$6 a hundred in carload lots, it will soon be difficult for the small country paper to continue.

SAN PEDRO.—The Union Oil Company has purchased 231 acres on the McDonald ranch, between Wilmington and San Pedro, for a consideration said to be \$275,000. A new \$3,000,000 refinery will be erected on this site. The land purchased is some of the most valuable in the harbor district. It overlooks the West Basin tidelands and lies between the Wilmington Road and the garden line of the Pacific Electric. The plans of the company are said to include a new subdivision for homes of employees at the refinery.

SAN PEDRO.—The Universal Chemical Company, organized by Jas. J. Hagan and others, has purchased a site for a manufacturing plant. Various chemical compounds are to be produced in the new plant, the first of which will be oil emulsion for destroying pests that damage fruit trees.

Connecticut

STAMFORD.—The Stamford Rolling Mills Company is finishing its last war contract in the Springfield plant. All work of this nature has been finished at the Fairfield Avenue plant, and there is work enough on "peace" materials to keep the shops going a couple of years.

Florida

PENSACOLA.—The Southern Fertilizer and Oil Company has purchased a factory site, which is to conduct the manufacture of oil and fertilizer from menhaden fish. The site consists of 95 acres at Grassy Cove, across the bay from Pensacola.

Idaho

HARLEY.—The North Star mill of the Federal Mining & Smelting Company, which has been closed down for a short time in order to install some new machinery and make necessary adjustments, has resumed operations. The entire plant is now in full operation. The material being handled at present is tailings.

Kentucky

IRVINE.—Reported Schell Syndicate, Lexington, will build refinery here to cost between \$500,000 and \$800,000 and give employment to nearly 1000 men. Work will begin in spring.

LOUISVILLE.—The L. W. Rendering Company will build a \$15,000 rendering plant to produce bone fertilizer, grease, etc. They will need 4 tanks, one press, one boiler, one engine, one elevator, one dryer and one evaporator. Fred E. Hoertner is president, and Fred Ehrhart, Norton Bldg., is superintendent.

LOUISVILLE.—The Royal Dutch-Shell Syndicate is planning the construction of a refinery to cost \$500,000 at Irvine, Ky.

Louisiana

NEW ORLEANS.—The Freeport & Mexican Fuel Oil Corporation has broken ground for its new plant on the Story plantation. An office building is being erected which will be followed by stills and tanks.

Maryland

BALTIMORE.—The Standard Grease and Glue Company will erect a \$100,000 plant in the Curtis Bay District for the manufacture of glue, soap and tankage. George A. Dabing of Baltimore will be president of the new company.

BALTIMORE.—The Union Soap Company, 214 North Pearl Street, plans the erection of a \$1,000,000 soap factory at Seam's Park, to take care of large foreign and domestic orders. The company has been in business for forty years and has a large factory in Baltimore. The company was recently reorganized with Horatio Turner, president, to \$75,000. He is vice-president; J. C. Hardy, treasurer, and Nathaniel Ewing, general manager.

Massachusetts

SPRINGFIELD.—The Filleroid Company will increase its authorized capital stock from \$1,000,000 to \$17,500,000, in order to provide funds for new buildings, machinery and other equipment.

WESTFIELD.—The Mari Paper Corporation of New York has leased Crane's upper mill on the Crayville Road and will begin the manufacture of onion skin paper, for which there is a growing demand. The Mari Paper Co. of New York is president; J. B. White of New York, treasurer; F. J. Marshall and Elwood Brinker, both of Easton, Pa., will be in direct charge of manufacturing.

Michigan

MUSKEGON HEIGHTS.—The Campbell, Wyant, Cannon Foundry has leased the foundry buildings of the Racine Boat Works of Muskegon, and is preparing them for immediate use in the manufacture of an engine casting.

The Enterprise Foundry is completing a three-story foundry for the production of plumbing fittings and castings.

Missouri

ST. JOSEPH.—The St. Joseph Tanning Company is constructing two additional double dry tunnels which will give the plant a daily capacity of 600 to 700 sides of leather.

Montana

BIG FORK.—Work on the construction of a large paper mill to be built by the Glacier Pulp and Paper Company, a new concern organized by St. Paul and Minneapolis financiers, will begin soon. The mill will be erected in the vicinity of large timber tracts controlled by the promoters, and will be operated by W. P. Snow of Big Fork.

The main office of the concern, whose capital is \$100,000, will be in Minneapolis. The new company is backed by E. Warner of the McGill-Valley Paper Company of St. Paul, G. M. and L. S. Gillette and F. Jordan of Minneapolis, and W. P. Snow of Big Fork.

New Jersey

NEWARK.—A fire of undetermined origin partly destroyed one of the buildings of the Charles Cooper Chemical Company in South Street on Dec. 26. The building was used for the manufacture of colloid.

NEWARK.—The Union Smelting and Refining Company and the Eagle Smelting and Refining Company of New York, which recently consolidated, have purchased a plot of eleven acres on St. Charles Street, and the new plant will remove to New York to the new site. A series of modern fireproof buildings will be erected, the first of which will cost \$250,000. Their products consist of white metal of all kinds, type metal, solder, etc. The New York office is in the Woolworth Bldg.

New York

BUFFALO.—The additions which are being made to the plant of the Schoellkopf Aniline & Chemical Works are being rushed as fast as possible. A five-story research laboratory and office building 53 by 150 ft., has been started, and work will be commenced soon on a large power plant, an ice manufacturing plant and a machine shop as adjuncts to the new manufacturing plant, which is being erected on the site of the Cooper Company has charge of the construction work.

LOCKPORT.—New York capitalists have been negotiating for the purchase of the plant formerly occupied by the Lockport Paving Company. It will be used as a pulp mill.

Ohio

CLEVELAND.—The Valley Smelting Company will erect smelting plant at Bradley Rd. and B. & O. R. R.; cost about \$125,000. The company was recently organized with a capital of \$250,000. Thirteen acres have been leased at the above location and the plant will be used for smelting and refining waste materials. The officers are Joseph Sillman, president; Charles O. Patch, vice-president and treasurer; J. D. LeBel, assistant secretary and assistant treasurer, and Harrison B. McGraw, secretary.

CLEVELAND.—The Western Chemical Company, of which we had a short note in our last issue, is incorporated under the laws of Ohio with a capital of \$25,000. The company is taking over the plant known as the Fleming processes, methods supposed to be shorter and less costly. The plant here has been running on Prussian blue, and marketing it in bulk form the past three months, and nothing else will be made at this plant. About 100 lbs. per day is the output.

The Pittsburgh plant is being designed for larger output, 300 lbs. per day, but there the dried and ground product will be produced. Also such chemicals as enter the products, and also dyes. George H. Fleming is president and P. L. Summers general manager.

COLUMBUS.—The Winslow Glass Company has closed down its plant permanently and will seek another location, because its glass supply has been cut off. The company has been located on the South Side for several years and employs 300 men in making milk bottles.

TELFEX.—The Standard Oil Company will spend about \$50,000 on new buildings to be erected here within a few months.

YOUNGSTOWN.—The Linde Air Products Company has purchased a site here and will erect a plant for the manufacture of oxygen, etc. About 25 men will be employed at the start.

Pennsylvania

BELLEFOUNTE.—The Hyde City steel rolling mills have been bought by a syndicate of capitalists headed by Dr. C. F. Hendrix. This firm has just completed work remodeling and enlarging the plant at a cost of approximately a quarter of a million dollars. The price paid was about \$50,000.

The mills are located about two miles from Clearfield and have not been in operation for five or six years. It is the intention of the new owners to convert them into a rolling mill for nickel steel bars and titan bronze tubing. Every effort will be made to have the plant in shape to begin operations early in the spring.

CHARLESTON.—The Charleroi plant of Macbeth Evans Glass Company resumed operations the last week in December, using oil, for which installation was made, in the place of gas.

DONORA.—The powdered coal system being installed in the Donora plant of the U. S. Steel Corporation is progressing rapidly. An oil system is also being installed. The systems replace gas, the shortage of which caused the mills in this section to shut down.

MIDLAND.—Announcement has been made that the Crucible Steel Company will build a new foundry here at a cost of \$75,000.

JOHNSTOWN.—The Cambria Steel Company will spend \$70,000 on the erection of two new blast furnaces and a new plant to manufacture car wheels. Ground has been broken for the furnaces and work will start shortly on the wheel plant.

PHILADELPHIA.—S. B. & B. W. Fleisher are erecting a two-story dye-house to cost \$70,000 at Twenty-fifth and Dickinson Streets.

PHILADELPHIA.—The Empire Pulp and Paper Mills Company of Montreal, Canada, has taken over and will operate the old Swanson Bay Pulpwood Manufacturing Company's plant. This plant was erected a few years ago, but only ran a short time. The new management plans to turn out 300 tons of pulp daily.

PHILADELPHIA.—The new firm of Monroe, Lederer & Taussig, which was formed by parties formerly with the Thompson Wood Finishing Company, will manufacture specialty paints and enamels for dipping, brushing, spraying for furniture manufacturers and allied trades. The new plant was expected to be in operation at the first of the year.

PORT ALLEGANY.—Dr. V. Mott Pierce, head of the Pierce Glass Company of Hamburg, has purchased the large plant built by the Glenn Glass Company at Port Allegany, Pa., which he expects to operate early in 1917.

SOUTH BETHLEHEM.—The Bethlehem Steel Company announced on Dec. 29 that work would start on a new hot and cold foundry with a capacity of 150,000 tons per annum, to be located at the eastern end of the Saucon plant. The cost of the building and equipment will be about \$750,000.

Utah

GARFIELD.—The American Smelting & Refining Company's sulphuric acid plant, which is to make sulphuric acid from the smelter gases, will be put in operation in a short time with an initial capacity of 100 tons per day.

MORONI.—The sugar factory of the People's Sugar Company is now under way. The site is situated one and a half miles south of Moroni in northern Sacate County on the Denver & Rio Grande Road. It is in the center of a large beet growing area, and is the first sugar factory to be erected in this district.

SALT LAKE CITY.—The Knight sugar factory at Raymond, Canada, is being dismantled by engineers of the Lynch-Cannon Eng. Co. of Utah and the Cannon-Swanson Sugar Mch'g Co. of Chicago, and will be shipped to Cache County, Utah, where several sites have been offered for its establishment.

SYRACUSE.—George M. Cannon, a real estate man of Salt Lake City, has been making considerable study as to the advisability of erecting a beet sugar factory in Davis County near Syracuse.

Washington

NORTH YAKIMA.—The Utah-Idaho Sugar Company is planning work on a \$1,000,000 plant in North Yakima. About

50 tons of lime per day will be needed during the manufacturing season and Mr. Horne, resident agent, has been receiving bids for this material. The silica content must not be over 2 per cent.

SEATTLE.—The American Nitrogen Products Company, C. P. Grant, manager, which has obtained the rights to use the patented electric furnace of F. H. A. Wielgowski, is putting up a temporary plant of 300 kw., capacity capable of expansion to 6000 kw., for the fixation of atmospheric nitrogen. Mr. Wielgowski is engineer in charge. It is understood that the company is seeking capital.

SEATTLE.—The president of a company owning a brewery in South Seattle announced recently that part of the plant would be equipped for manufacture of industrial alcohol, following the suggestion of an Eastern manufacturer of automobiles. The alcohol plant will be in operation in a few weeks.

STUMNER.—The Northern Board & Paper Mills will erect a 35 x 100-ft. addition to take care of increased demand. The present output of paper board is 28½ tons per day.

West Virginia

WHEELING.—Contracts are being let for work on an \$8,000,000 sheet steel plant to be erected by the Whitaker-Glessner Co. at Beech Bottom, near here.

Wyoming

BASIN.—John C. Roberts, manager of the Consumers Oil & Gas Company of Billings, Mont., has announced that his company will start construction in the spring of a large oil refinery at Basin with a capacity of 1000 barrels per day.

Canada

CHICOUTIMI, QUE.—The Chicoutimi Pulp Company will move in addition to its plant here and increase its output from 30,000 to 130,000 tons of pulp per year.

COBALT, ONT.—The Davidson Gold Mines, Ltd., has completed negotiations with the London financial house for the issue of a large block of treasury shares to provide funds for the erection of a large mill.

QUATSINO SOUND, ONT.—The Colonial Pulp & Paper Mills, Ltd., will build here a sublimé plant to have a daily capacity of 120 tons. The first unit will have a daily capacity of 60 tons. The installation will be completed in about a year.

VANCOUVER, B. C.—The American Consol in British Columbia has sent to the Board of Foreign and Domestic Commerce the following note in regard to the purchase of a smelter by American capitalists:

"The Ladysmith smelter, formerly operated by the Tyee Copper Company, an English concern, has been purchased by American capitalists, and as soon as extensions and improvements involving an outlay of \$100,000 can be made the plant will be put into operation.

"Efforts have been made for some time by local organizations interested in the development of mines on Vancouver Island to induce the Provincial Government to take steps for the opening of the Ladysmith smelter. With its extensions it will soon be in full operation and will employ more than 100 men. Facilities provided by the extensions will enable it to turn out blister copper, whereas formerly it could produce only copper matte. Mine operations on Vancouver Island have been sending their ores to the smelter at Tacoma, Wash. for treatment, and with the operation of the Ladysmith smelter the necessity for this will be obviated.

"It is stated that the Tacoma smelter is very busy, and if it is offered more business it can handle the mine output on Vancouver Island would find their smelter facilities curtailed without some arrangement on Vancouver Island.

"The new enterprise is to make the plant thoroughly modern and install converters. Blister copper, instead of being sent out of the Province, probably will be treated by large electrolytic refineries. The capacity of the Ladysmith smelter is 500 tons, but will be greatly increased."

ST. JOHN, N. B.—The Partington Pulp & Paper Co. (Ltd.), of St. John, New Brunswick, has sold its mill and timberlands to interests in the United States for about \$3,000,000. The purchase includes 372,000 acres of spruce and fir wood and 1,000,000 ft. of hardwood. The output of timberland comprises nearly 30,000,000 cords of wood. The purchasers are incorporating a new company, which proposes to start an early start to increase its output of the Partington sulphite mill from 60 to 80 tons of bleached sulphite pulp daily. It is understood that the principal object of the purchasers was the acquisition of the timberlands.

Manufacturers' Notes

RUST PREVENTIVE PAINTS.—The Harrissburg Chemical and Paint Company, Inc., 917 Hemlock Street, Harrisburg, Pa., which recently enlarged its plant is specializing on Rust Prevento Oil, Rust Prevento Paints and Damp Prevento Concrete Dressing. These products have been the subject of various tests in actual service, and have proven satisfactory preventives.

The oil can be applied either upon new metal or metal that is already corroded.

Tests have been made during the past six years, under all conditions, which have given a wide range of the various ways in which it can be used, not only upon iron and steel, but upon tin, nickel plating, etc.

PULVERIZED COAL EQUIPMENT.—The Fuller Engineering Co., Allentown, Pa., have contract for pulverized coal equipment for American Steel and Wire Co., Donora Steel Works, Donora, Pa., in connection with eight 60-ton open-hearth furnaces, for pulverized coal equipment for heating furnaces of the American Works of the American Steel and Wire Co., at Cleveland, Ohio, and pulverized coal equipment for two open-hearth furnaces in No. 1 Lehigh plant of the Bethlehem Steel Co., South Bethlehem.

SOUTHERN STATES ENDORSE MUSCLE SHOALS FOR GOVERNMENT NITRATE PLANT.—The Southern Congress unanimously endorsed resolutions on Dec. 13 endorsing Muscle Shoals as the best available site for the government nitrate plant. The committee's recommendation was made after the endorsement of the South for the Muscle Shoals location. Muscle Shoals has been described in this journal in connection with the West Virginia of the American Cyanamid Co., to build a factory there and supply the government with all requirements of nitric acid. It is the only place in the South where 120,000 ft. of pulp have been developed 24 hours a day. It is the only Southern location that has received any consideration from the War Department engineers.

PUBLISHERS IN TEXAS AND LOUISIANA CONSIDERING ESTABLISHMENT OF PAPER MILLS.—In many parts of the country publishers have held meetings to consider the advisability of establishing cooperative paper mills, to counteract the high cost of paper. In California, West Virginia and other states the movement has been on foot for some time. The latest section to take up the question includes Texas and Louisiana. After the holidays there were over a meeting of the publishers of Texas and Louisiana was to be held in Beaumont to discuss the feasibility of the plan and to gather authentic information. The value of gulf coast products for making print paper. Sweet gum wood is mentioned as one of the valuable raw materials from which paper can be made.

SOUTHERN TURPENTINE PRODUCERS ORGANIZE.—Turpentine manufacturing interests of Louisiana, Mississippi and Texas met in New Orleans Dec. 20 and decided to organize the turpentine producers association, to be operated on a similar basis to that of the Southern Pine Association.

Charles F. Spoh of Washington called the conference. H. H. Gordon, president of the Independent Naval Stores Company of Lake Charles, La., presided. West Virginia and other states the movement has been on foot for some time. The latest section to take up the question includes Texas and Louisiana. After the holidays there were over a meeting of the publishers of Texas and Louisiana was to be held in Beaumont to discuss the feasibility of the plan and to gather authentic information. The value of gulf coast products for making print paper. Sweet gum wood is mentioned as one of the valuable raw materials from which paper can be made.

Among prominent naval stores producers present were: J. N. Corbett, Fullerton, La.; E. M. Pringle, Glen Mire, La.; V. G. Phillips, Provencal, La.; W. A. Hood, Pine Bar, La.

PLANT FORCED TO LEAVE COLUMBUS.—The Winslow Glass Company, Ohio, which employs 300 men in making milk bottles has been forced to shut down its plant and move its operation owing to the shutting off of its gas supply.

SHORTAGE OF NATURAL GAS IN INDIANA.—The blowing of colored glass will be discontinued at the plant of the Johnston Window Glass Company, Hartford, Ind., on account of the unavailability of the natural gas supply, the only fuel which can be used to advantage in the manufacture of this article. About fifty employees will be thrown out of work in this line by the decision of the company.

ENGLAND WILL BUILD FOR LARGE CHEMICAL TRADE IN MEXICAN WARE.—That England will make a strong endeavor to secure a big export business in chemicals after the war is the belief of those familiar with conditions and developments in that country. It is estimated that the free-trade policy will be abandoned as duties are considered essential for the building up of the chemical industries. There has been a remarkable development in chemical manufacturing in England since the war began, and many factories which are supplying war needs can be converted to making various products.

1916 GREATEST EXPORT YEAR.—Manufactures were exported from the United States in 1916 to a value greater than the value ever exported by any country. It is estimated that the year's total was considerably in excess of \$3,000,000,000. The highest export record ever made by Great Britain was \$2,012,000,000 in 1913, the year immediately preceding the war. Prior to the war, the United States held third rank. In 1914 our exports amounted to \$974,000,000 and in 1915 to \$1,784,000,000. A statement of the National City Bank is as follows:

"The growth in exports since the beginning of the war is, of course, due in a considerable degree to the demands for strictly war material, explosives alone being for 1916 approximately \$675,000,000. Shell tubes for the manufacture of shells \$225,000,000; while in many other articles, such as automobiles and various articles of iron and steel there is a large increase, although just what proportion of the growth is due to the demands of the war can only be estimated. Of iron and steel manufactures of all kinds the exports of the full year show a total of approximately \$400,000,000 against \$200,000,000 in 1914."

In the view of the bank, the experiences of the year just ended demonstrated the ability of the manufacturers of the United States to supply in larger proportion of the manufactures entering world commerce than they have in the past, since the total value of the manufactures which were exported in 1916 was approximately 40 per cent of the total manufactures entering international trade in normal years as against approximately 15 per cent which this country's manufacturers supplied in the year just preceding the war. The report showed that prior to the war the percentage which manufactures formed of the domestic exports of Great Britain was 79 per cent, Germany 67 per cent, France 58 per cent, and of the United States 47 per cent. Manufactures formed 15 per cent of American domestic exports in 1880, 21 per cent in 1890, 35 per cent in 1900, 40 per cent in 1910, 49 per cent in 1913 and approximately 66 per cent in 1916.

MEETING OF TUNGSTEN PRODUCERS.—At a meeting of a special committee of tungsten producers of this State, appointed by Frederick Wells, chairman, the following members, Harold Boericke, Primos N. & M. Co., Boulder; J. A. McCormick, Vasco Mining Company, Boulder; Robert M. Kennerly, Colorado Tungsten Company, Denver; J. G. Clark, Boulder Tungsten Produce Co., Boulder; William Leach, Platt Rogers Mfg. Co., Boulder; Forbes Rickard, Rugged Tool Co., Denver; Platt Rogers, Rogers Patent, Denver; Horace Holmes, Luckie 2 Mfg. Co., Boulder; Geo. W. Teal, Tungsten Metals Co., Boulder; Wm. Cowley, Long Chance Mfg. Co., Nederland; Nelson Franklin, Tungsten Ores Co., Rollinsville; N. H. Brown, Mojave-Boulder Tungsten Mfg. Co., Sugar Creek. It was decided to call a meeting of the tungsten producers of the United States to convene during the annual meeting of the Colorado Metal Mining Association, to be held in Denver Jan. 9, 10 and 11, 1917. This meeting was for the purpose of calling a conference of the tungsten producers of the country to formulate a plan for concerted action in all matters affecting the industry and especially in an effort to secure as early as possible favorable action on the part of the proposed tariff Commission in behalf of a duty on tungsten and the products thereof.

SALES CONVENTION OF THE KENNEDY VALVE MANUFACTURING COMPANY.—The sales force of The Kennedy Valve Manufacturing Co. convened at its plant in Elmira, N. Y., on Dec. 14 and 15. A most interesting and profitable convention was held. It was the first time that many of the salesmen had met the new sales manager, Mr. J. L. Peden. On the morning of the first day the entire company of salesmen and managers made a tour of inspection through the company's plant, which is located on a plot covering twenty acres. Numerous arguments were heard pro and con, and in the evening a dinner was given at the Country Club in Elmira. The meeting was unanimously voted to have been the most successful ever

held by The Kennedy Valve Manufacturing Co., and reflected great credit on the several executives who had it in charge.

FRENCH CONCERN WANTS CATALOGS.—Mr. Jacques Vieyra, 24 Rue de Lubeck, Paris, France, is desirous of receiving catalogs and literature on electric motors and supplies (not motors or generators), laboratory supplies for industrial, chemical and metallurgical work, with a view to taking up the importation and the sale of the portion of the goods mentioned throughout France and her colonies.

FOREIGN TRADE OPPORTUNITIES.—The following opportunities for foreign trade have appeared in recent Commerce Reports:

23.382.—A firm in Spain wishes to represent American manufacturers and exporters of dyestuffs used in coloring cotton, woolen and silk textiles. The firm also desires to purchase on its own account. Cash will be paid against documents. Quotations should be made c. i. f. destination. Correspondence may be in English. Reference.

23.385.—A man in Spain wishes to purchase dyestuffs for the textile industry. Quotations should be made f. o. b. New York or c. i. f. destination. Correspondence may be in English. Reference.

23.387.—A man in Venezuela wishes to purchase machinery for making glue, as a by-product of a tannery. Machines are desired with a capacity of about 275 lb. per day. Correspondence is preferred in Spanish, but English is all right.

23.394.—A man in the British West Indies desires to be placed in communication with American manufacturers of small power steam mills and fiber vessels of cut. capacity.

23.396.—A business man in Switzerland would like to purchase several tank cars, with a capacity of 4000 to 6000 gal. for oils, petroleum, etc. The cars are to be constructed in compliance with the specifications of the Swiss Federal Railways. Quotations should be made c. i. f. European port. Cash will be paid against documents. Correspondence should be in French or German. Reference.

23.401.—A company in India wishes to receive catalogs and full information from American manufacturers of modern aerated water plants. Quotations are desired c. i. f. foreign port. Correspondence may be in English. Reference.

23.403.—A man in Spain is desirous of representing American manufacturers and exporters of varnishes, colors and drugs. Correspondence may be in English. Reference.

23.424.—An engineer in Norway desires to secure a sole agency for the sale of leather and materials of all kinds for use by engineers and builders. Quotations should be made f. o. b. American port or c. i. f. destination. Correspondence may be in English. Reference.

LEATHER TRADE.—The Swiss Government, according to the U. S. Consul at Berne, has undertaken the protection of the leather supply of the country, and its first step has been to place the country's shoe factories under the control of the Department of Agriculture and the War Office, to fix maximum prices for the shoe and leather trade and issue directions to the tanners regarding the preparation of the hides and skins. Licenses hereafter issued by the Swiss Military Department will enable business men to buy the skins and hides of animal slaughter at prices and conditions fixed by the government, but will insure deliveries of stocks held by tanners, as the law provides that stocks cannot be withheld from buyers with licenses. Only goods that cannot be used in the country may be exported, according to the provisions of the new law. The maximum prices do not affect running contracts.

MEETING OF OBEX LABORATORIES.—A meeting of the stockholders of The Obex Laboratories Co. was held at the offices of the company, Marietta, Ohio, on Tuesday, Jan. 2. Mr. G. A. Vallee, president of the company, read a report summarizing the year's work, which report included a high and successful year. It was voted to change the name of the company to "The Obex Company," and the capital stock was increased from \$200,000 to \$400,000. A new board of seven directors was elected, consisting of the following members: Judge E. B. Follett, R. M. Noll, J. H. McCoy, C. J. La Vallee, C. E. LaVallee, G. A. Vallee, all of Marietta, and A. Alexander of New York City. All of the products of the company are sold exclusively through the National Gum & Mfg. Co.

ANNUAL CONVENTION OF VANADIUM-ALLOYS CO.—On January 3, 1917, at the Pittsburgh Athletic Association occurred the Annual Convention and Banquet of the

Sales Representatives of the Vanadium-Alloys Steel Company, Pittsburgh, Pa., which manufacture high speed, chromium alloy tool steel, and some very interesting topics were thoroughly discussed, the most prominent being a paper on "Crucible Tool Steel," read by Roy C. McKenna, president of the company. The following day a trip to the mills at Latrobe, Pa., was enjoyed by all of the representatives, after which the salesmen returned to their respective posts in the United States and Canada.

Manufacturers' Catalogs

HUMIDITY AND TEMPERATURE REGULATING DEVICES.—Bulletin No. 102, containing 48 pages of description and illustrations of controlling devices to meet all commercial requirements has just been issued by the Carrier Engineering Corporation, 39 Cortlandt Street, New York. The introductory pages explain how a system of control is dependent upon various factors, chief among which are the number and sizes of rooms, their contents, arrangement of machinery, sources of heat and moisture, direction of air currents and the exact humidifying, dehumidifying, heating, cooling and drying or combination of these to be accomplished.

THE VANADIUM-ALLOYS STEEL COMPANY.—Pittsburgh, Pa., has issued a folder descriptive of Vasco-Marvel, a semi-high-speed steel. This folder contains much information of interest, together with the High Speed Steel Standard Classification of Extras adopted July 22, 1915.

The Railroad Congestion

The railroads are found to be quite incapable of handling all the freight offered them, and the steel industry suffers more than other industries. Shipments are greatly interfered with as to both volume and celerity, and production is measurably reduced. It is natural that the steel industry should suffer most, for there are no really large industries that involve the movement of so much material in proportion to the finished output. The number of ton-miles of freight involved in placing a ton of commercial steel at its point of ultimate use is enormous. About four-fifths of the iron ore is moved a great distance, fully two tons of ore to a ton of finished product, while most of the coke is moved a considerable distance, about ton for ton. Then there is coal and limestone, which does not appear in the finished product, besides slag that must be carried away. Between works there is considerable movement of pig iron and scrap, as well as of partly finished material. Thus the railroads are called upon to do a great deal of work, and the least insufficiency in performance is necessarily reflected in the operation of the industry.

The efficiency of the railroad depends upon much the same items as does the efficiency of a steel mill. The blooming mill, for instance, must be supplied with ample power. The engine must be capable of delivering enormous power at slow speeds for the first pass of the ingot, like a locomotive starting a train, and it must be capable of high speeds for the final pass, just like the locomotive when it has a clear track before it. If either engine is inadequate for either the slow or the fast service the total capacity of the unit is reduced. There must be storage facilities for ingots and blooms, just as the railroad must have storage room at its terminals, and there must be a sufficient number of passes in the blooming mill as there must be a sufficient number of tracks on the railroad.

There is another line of analogy between the rolling mill and the railroad. Given certain specifications the rolling mill can produce a very large tonnage, and the customers who have filed those specifications are well satisfied. Other customers, the filling of whose specifications requires roll changes, sometimes have occasion to wait. It is related of a relatively small western road that while some of the shippers depending upon it are greatly incommoded the road is carrying the record tonnage of its history. At one junction point it is embargoed except as to train loads. The connecting line will accept train loads and nothing else, and it chances that this road is able to make up many such train loads, hence its large tonnage while many customers are suffering.

The experience of the steel mills in the past two or three weeks has shown conclusively that the weak element in the railroad equipment is the motive power. For a time car shortage was blamed, the mills not receiving sufficient empty cars. That could have been due to a variety of causes, but of late the supplies of cars at mills have increased but the facility of movement has decreased. When the cars are loaded the railroads are unable to carry all of them away, and insufficiency of motive power is now clearly indicated. It is particularly unfortunate that the difficulty should be at this point, for the reason that under the severe duties imposed the efficiency of the motive power decreases week by week, locomotives requiring repairs for which their time cannot be spared. Terminals and sidings do not wear out, nor do cars in any short period of time. Thus there is little prospect of material relief in the railroad situation in the near future.

No considerable number of new locomotives is to be delivered to the railroads in the near future. Statistics recently gathered by the *Railway Age Gazette* indicate this. It may be assumed that the locomotive shops had scarcely any orders on their books Jan. 1, 1915. In the two years since that date the domestic and export locomotives booked by shops in the United States and Canada totaled 7397, while the locomotives produced totaled 6160, leaving 1237 on books at the beginning of this year, and probably more than half of these were for export. As there are in service in the United States about 65,000 locomotives there should be thousands added rather than hundreds.

The Rat Problem

Somebody guesses that a rat census of the United States would show as large a number as that of the population; that it would be above the hundred million mark. Like flies and mosquitoes, they have not a single valuable quality and they not only carry disease but they consume vast quantities of human food. They are bearers of the contagion of bubonic plague and leprosy and they are the enemies of mankind. Indiana and Michigan offer pecuniary inducements to their citizens to kill rats. On Feb. 12 there is to be held a dead rat fair in Boston with prizes offered at the several "sanitary yards" of the city to citizens who excel in the de-ratting, the un-ratting, or ent-ratting art; even the word has not been coined yet. The prizes are to be given by the Women's Municipal League and Mayor Curley gives encouragement to the effort.

All this is good, but it is likely to be sporadic in Boston and local in Indiana and Michigan. The great nation of rats, engaged in seeking life, liberty and the pursuit of happiness need not despair of the wrath of Boston or the legislation of the Middle West, provided they understand human nature, and with this they seem to be tolerably familiar. They are not so closely attached to their homes as are their feline enemies and on slight provocation they move. They travel easily by night, they have no loads of furniture

to carry with them, and the proprieties of sanitation do not interest them at all, save as things to be avoided. We do not think the death-knell of the species has sounded yet.

Now let us see if we may not find a profitable use for dead rats, in which the problem of immediate transportation is not involved. If we make of rat-killing a profitable sport in which everyone so inclined may engage at his leisure, the death-curve among the species may grow sharper than the curve of increase. Of course, it takes a chemist to solve the riddle; in this instance a leather chemist. The solution is, tan their hides. Animals with thick fur have poor hides, those with thin fur produce durable, strong leather. The rat has thin fur. They are large enough for gloves, mitts, soles, inlays, buttons and a vast number of other uses to which leather is put. The skins are worth 10 cents each, easily. They may be salted down and nailed up against a barn door and dried. They will keep indefinitely. When a farmer has a couple of dozen set aside they may be carried to town in a basket and disposed of to the postmaster for \$2.40. Five thousand skins a day would keep a tannery running profitably. The government would increase its parcel post receipts and do a grand service in that thing for which we lament we haven't the word yet—ent-ratting, let's call it. It would be an act of altruism to buy and wear or use articles made of ratskin, which we offer as the cheapest and easiest method of achieving virtue that has been offered in a long time. If ratskins grew scarce and the tannery could operate only on part time, the price would go up and they would become fashionable. The tariff commission would then have an interesting problem to solve whether foreign ratskins should be admitted free of duty or not. When the problem reached Congress it would serve the excellent purpose of breaking down party lines—a consummation always devoutly to be wished for.

As for the cat and rat farm wretch who would raise these animals in captivity, selling the skins and feeding the carcasses of cats to rats and rats to cats, it should not only be discouraged but legally prohibited; strengthily undersaid. Rat catching must remain a sport.

Changes in Steel Demand

It will be recalled that 1906, one of the best years the steel trade has passed through, with respect to there being a sustained and heavy demand, was a year of much new construction. The railroads were all active in laying new track and in adding to their rolling stock. There was much new construction in bridges and buildings. Conditions since the war started have been altogether different. New construction has been light, except where stimulated by the existence of war orders, while there have been large exports of steel. There are as yet no statistics of steel production last year, but it is of interest to compare the distribution of steel production, as to the various finished com-

modities in 1906 and 1915, as shown by the following table:

Percentages of Iron and Steel Production

	1906	1915
Rails	20.4	9.0
Shapes	10.8	9.9
Plates	12.9	12.4
Sheets	5.5	8.0
Tin plate	2.9	4.5
Wire rods	9.5	12.6
Bars	20.2	16.9
Skelp	7.8	9.4
Hoops	.9	1.2
Bands and cotton ties	2.1	1.8
Export billets, etc.	1.0	2.3
Miscellaneous	6.0	12.0
	100.0	100.0

The production of rolled material increased from 19,588,468 gross tons in 1906 to 24,392,924 tons in 1915, or by 25 per cent. As the proportion of rails was decreased by more than one-half, the actual tonnage decreased. Railroad buying in general decreased in somewhat the same manner. Another large decrease was that in bars, while structural shapes showed a small decrease. There was a slight decrease in the proportion of plates, and as shipbuilding was particularly active in 1915 it may be assumed that the use of plates in structural work underwent a proportionate decrease, as was the case with shapes.

The increase in the proportion of sheets, tin plates and hoops is not to be ascribed to the war but is rather a part of a continual expansion in the use of these light products, which are constantly being employed in new uses. All studies of steel production statistics indicate that year by year steel is entering more into the common everyday use of the people at large. There was a time, in the decade of the eighteen-eighties, when the railroads were credited with consuming fully half the iron and steel produced in the country. As the theoretical per capita consumption increases it becomes more and more a real per capita consumption and not merely an average.

The Engineer in Americanization

Last week Mr. and Mrs. Vincent Astor and the Immigration Committee of the Chamber of Commerce of the United States gave a dinner at the Astor home "to the engineers of America," the subject of after-dinner discussion being the part of the engineer in industrial Americanization. There is no more important subject for engineers to discuss at present, but the many digressions of a few of the speakers on that occasion clearly showed that the recognition of the real meaning of "industrial Americanization" is not yet universal even among prominent engineers.

The future of the industries of this country depends to a large extent on the immigrant. No detailed statistics is needed here to show that while the invention and installation of labor-saving machinery has made rapid progress, the need for more and more men has neverthe-

less simultaneously progressed at an increasing rate. Nor is the number all that is needed. We have emphasized before in these columns that the thousands and thousands of immigrants now working in contractors' gangs and unable to speak English represent an immense untouched industrial asset. Every one of them has a history and many of them have a trade and are masters at their trade, but so far we have been unable to make right use of them.

The industries owe to the immigrant laborer more than a full dinner pail. What is his due in the widest sense may be summed up in the term "Americanization." Above all he must learn English, since personal contact is everything. But the conditions of work and the conditions of living also count. The slums must go. There is something radically wrong with industrial works that cause slums to come into being or to be maintained. But the first step—the step that counts and that is most difficult—is to teach the immigrant English. How can it be done?

What really wonderful work is possible along these lines has been shown in the past nine or ten years by the International Committee of Young Men's Christian Associations (Industrial Department) which has enlisted 4500 college men who are weekly reaching 100,000 working men and boys in volunteer service. These young college men from 250 colleges are teaching English to foreigners, instruction classes of American workmen, etc. What this means to the immigrant is clear; it is his first chance to come into sympathetic contact with Americans.

But it is even more remarkable what this work means to the young college man. This work reacts on him. To sow love is to harvest love. It means that a thousand men are graduating from our American colleges each year after having secured in this way a vision of their service opportunities and responsibilities and some experience in handling men with intelligence and sympathy.

Thus the Americanization movement is bound to react on the Americans. If it was emphasized by one speaker at the Astor dinner that the first thing to do is to Americanize the Americans, the work with the immigrant is one means of changing Americans into better Americans, of creating a broader vision of the responsibilities of service to mankind. To quote another speaker it is well enough to urge universal military service, but should we not emphasize "service" rather than "military"? The Americanization movement needs the help of everyone. Americanization should not be left so much to the individual employer's paternalism, but should rather become a legitimate function of every great industrial organization. And because this is so it needs the help of the engineer with his scientific methods of organizing.

The famous Astor home at 840 Fifth Avenue has seen many a brilliant fashionable function of ultra-fashionable society, but it has never been filled more freely with the true American spirit than at these dinners tendered by its present masters in the furtherance of industrial Americanization.

Determination of Phosphorus in High-Speed Steels

To the Editor of Metallurgical & Chemical Engineering

Sir: The following modification of the present methods for the determination of phosphorus in high-speed steels has been found by the writer to be accurate and rapid, excellent results being procured on government standards containing various amounts of tungsten and vanadium.

Dissolve two grams of the sample in 1-3 aqua regia, and when the solution is boiling quietly add a few crystals of potassium chlorate. Evaporate to about 20 c.c. Then remove from hot plate, add 40 c.c. of water, cool under tap and filter, washing twice with 1-1 HCl. Next evaporate the solution to the "basic ring." Again remove from the plate, wash down sides of beaker with about 25 c.c. of water, cool and filter. Transfer solution to Erlenmeyer flask and after neutralizing with 10 c.c. of ammonia and adding 15 c.c. nitric acid, precipitate immediately with molybdate solution. If vanadium is present, reduce with 5 c.c. of 3 per cent sulphurous acid just before adding the molybdate. Allow solution to stand 45 minutes after thoroughly shaking. Then filter, and determine phosphorus by titration with standard acid and alkali solutions.

EDWARD C. KRAUS.

Laboratory Atlas Steel Co.,
Punkirk, N. Y.

A Story

Anent the Editorial on Niagara Power Crisis in "Metallurgical & Chemical Engineering," Dec. 1, 1916

To the Editor of Metallurgical & Chemical Engineering

SIR:—Once upon a time there was a farmer who had a dairy ranch. He was not what might be called a scientific farmer, rather one governed by the rule of thumb. By dint of hard-earned experience he had found that his stock of cows flourished if he gave them a mixed diet. They grew sleek under it and delivered rich milk.

Part of the mixed diet which he offered them he raised himself on his ranch, while the other part—a special brand—he bought from an importer.

After our farmer had spent all summer on his country place he decided when autumn came to enjoy the winter months elsewhere.

To be sure that his farm hand would continue the successful feeding of his cows and that the creatures might flourish and continue delivering the same quality of rich milk he prepared a carefully and specifically worded memoranda of instructions.

Feeling assured that all was well planned for the coming winter, he departed for the city to enjoy the products of his ranch, together with his contented customers there.

As time drifted along, there gradually was expressed to him one complaint after another by his customers over the quality of the milk that was delivered to them and finally the quantity also decreased to such an extent that a number of customers were left completely without the white beverage.

Dismayed and chagrined our farmer took an early train for his ranch.

On reprimanding his farm hand for the bad quality and decreased quantity of milk he had delivered, the farm hand took his employer to the written feeding in-

structions carefully nailed on the wall and from there to the barn and there showed that the imported feed had come to an end. The instructions on the wall did not specify any alternative in case one or the other of the feeds would run short.

The farm hand offered the written instructions and the lack of imported feed as excuses for the shortage of milk and for the inferior quality. He had never considered applying himself any remedy nor had he considered advising with his employer, since no such proviso was made on the written instructions.

The farm hand happened to be a stickler for the letter and received his just reward for being so unteutonic in his management. He was fired!

By naming the "ranch owner," "Congress;" the "customers," "the people;" the "cows," "electrochemical industries;" the "ranch," "Niagara Falls;" the "feed," "hydroelectric power;" and the "farm hand," "Baker," the story is pretty nearly true—all but for the "fired."

San Francisco, Cal.

Legal Status of Flotation Processes

To the Editor of Metallurgical & Chemical Engineering

SIR:—The decision handed down by the United States Supreme Court in the case of Minerals Separation, Ltd., et al. versus James M. Hyde is of importance quite as much from the light it throws upon the unnecessary impediments to the normal growth of industry which arise from our present system of issuing and adjudicating patents as from any bearing it may have upon the development of ore-dressing practice.

The patent upon which the charge of infringement was based, and the validity of which was denied, by the defendant is U. S. Patent No. 835,120. It will readily be understood that after 800,000 improvements in apparatus or processes have been covered by patents in this country, further "improvements," as we ordinarily call inventions, as termed in patent law, are likely to be so restricted in scope as to require very close and exact definition.

The patent in suit has been claimed by its owners to be a broad basic patent covering practically all of the commercially profitable methods of concentrating ores by the flotation processes. The specification of the patent relates that "we have found that if the proportion of the oily substance be considerably reduced, say to a fraction of 1 per cent on the ore, granulation ceases to take place, and after vigorous agitation there is a tendency for a part of the oil-coated metalliferous matter to rise to the surface of the pulp in the form of a froth or scum." The claims all call for agitation as the means of forming a froth with the use of "a small quantity of oil," or with oil, or oleic acid in amounts less than 1 per cent of the weight of the ore treated. A study of the "file wrapper" correspondence between the Patent Office and the inventor's patent attorney shows that the inventors applied for a claim covering "the process of concentrating ores which consists in separating the mineral from gangue by coating the mineral with oil in water containing a fraction of 1 per cent of oil on the ore, and recovering the oil-coated mineral," and a claim wherein was described a process in which the pulp was to be subjected to the action of compressed air for a separation of part of its valuable constituents after being treated by the methods de-

scribed in the other claims. The Patent Office refused to grant the claim not specifying agitation as the means of producing the froth, and also refused to grant the compressed air claim as not coming within the patent, but constituting an alternative concentration method.

The most marked feature of the decision granted by the Supreme Court is that it differs with all other decisions which have been passed upon the validity or construction of this patent. The United States Patent Office is held to have erred in granting too broad a patent. By inference, the German Patent Office was wrong in refusing to grant this same patent, which it held to make no new disclosure or contribution to the art of ore dressing. The District Court of Montana is held to have been in error in holding valid those claims of the patent which are not restricted to the use of a fraction of 1 per cent of oil. The District Court of Delaware made the same error, and also in the Miami case held the patent to cover operations which do not include agitation as defined by the Supreme Court as used in this patent. The Circuit Court of Appeals for the Ninth Circuit is reversed in its decision that the patent is invalid as a whole.

The Supreme Court says in part in the decision delivered by Mr. Justice Clark: "While we thus find in favor of the validity of the patent, we cannot agree with the District Court in regarding it valid as to all of the claims in suit. As we have pointed out in this opinion, there were many investigators at work in this field to which the process in suit relates when the patentees came into it, and it was while engaged in study of prior processes that their discovery was made. While the evidence in the case makes it clear that they discovered the last step which converted experiment into solution, 'turned failure into success' (the Barbed Wire Patent, 143 U. S., 274), yet the investigations preceding were so informing that this final step was not a long one, and the patent must be confined to the results obtained by the use of oil within the proportions often described in the testimony and in the claims of the patent as 'critical proportions' amounting to a fraction of 1 per cent on the ore."

The Supreme Court clarifies the issues of the case by clearly defining the scope of the process in these words: "The process of the patent in suit, as described and practiced, consists of the use of an amount of oil which is 'critical,' and minute as compared with the amount used in prior processes, 'amounting to a fraction of 1 per cent on the ore,' and in so impregnating with air the mass of ore and water used, by agitation—'by beating the air into the mass'—as to cause to rise to the surface of the mass, or pulp, the froth, peculiarly coherent and persistent in character, which is composed of air bubbles with only a trace of oil in them, which carry in mechanical suspension a very high percentage of the metal and metalliferous particles of ore which were contained in the mass of crushed ore subject to treatment."

Agitation, as the term is used in the patent, is thus defined in the complainants' own language as being such rapid mechanical stirring "by beating the air into the mass" as to impregnate the mass of ore and water with air sufficient to cause a very high percentage of the valuable minerals to float as a froth. That is undoubtedly the sense in which the patentees used the term "agitate to produce a froth" in this and allied patents in which no other means is mentioned by which the air necessary to produce a froth is to be introduced into the pulp. This patent specifically disclaims the generation of a gas within the pulp by the use of sulphuric acid as coming within the scope of the patent, and as has been previously pointed out the Patent Office

refused to grant the claims calling for no means of introducing the froth-producing gas, or making compressed air the means of producing a froth.

The pneumatic process of flotation concentration which has come into such extensive use, and is preferred to the agitation froth process by many operators, was broadly described in a patent taken out in Great Britain by Minerals Separation and Theodore J. Hoover in 1910. This patent broadly describes a process for concentrating ores by introducing a gas of any kind through a permeable medium into an oiled ore pulp for the purpose of causing the oiled mineral to float as a froth and overflow and thereby be separated from the gangue minerals. Several methods were described for accomplishing this result and a number of forms of apparatus were described. It is understood that when an inventor in this country who had independently discovered this same process applied to the United States Patent Office for a patent covering this method, he was denied a patent on the ground that the process had been disclosed in the British patent and was already open to free use in this country, as its original inventors had taken out no patent covering the process in the United States.

The claim has been made that the process just passed upon is a broad basic patent covering the production of a mineral-bearing froth as a means of separating the metalliferous contents of an ore from the gangue, and throughout the suit the witnesses for the complainant constantly described the result of this process as a froth while no other process was held to make a froth. It is interesting to note that in 1910, five years after the alleged discovery of the process of the patent in suit, Minerals Separation took out two patents for processes in which it was said that there were already a number of well-known processes for producing concentration by the means of froth, stating: "The processes employed to obtain these froths or scums may be any of the well-known flotation processes as described, for example, in"—then is given a list including the patent under discussion and two patents preceding it, one of which is the Froment process, which was relied upon by the defense as one of the most important anticipations of the patent in suit. The Froment process patent was taken out about three years before the alleged invention of the process of the patent just passed upon by the Supreme Court. It was testified by one of the alleged inventors of the agitation froth process that he had in his safe for over two years preceding the alleged invention of the agitation froth process a report by Alcide Froment describing how his process should be worked, and that this report had never been seen by anyone save himself and the other two alleged inventors of the agitation froth process. The Froment pneumatic process was patented in Great Britain but not in the United States.

The decision of the Supreme Court seems to have been granted upon the assumption that there is a "critical proportion of oil," and that this critical amount is "a fraction of 1 per cent of the weight of the ore treated. The term 'critical proportion of oil' is evidently used to convey the impression that there is a proportion of oil which will result in the production of a froth while more than that amount will not. The further impression was created that this critical proportion is "a fraction of 1 per cent of the weight of the ore treated." If these assumptions are correct it is to be assumed that the earlier processes referred to in the 1910 patents as "well-known flotation processes which produce a froth" must have used this critical proportion.

The defense introduced into evidence a number of tests using more than 1 per cent of oil which made as thick and permanent a froth as is obtained with less than 1 per cent of oil and yielded as good concentrates

and as high recovery. These tests were all made in an apparatus which it was conceded by all concerned was the best to be used in determining what could be done on a commercial scale, but these tests were objected to by the complainants as being mere laboratory tests. Several of these tests were repeated in the court room. Judge Gilbert in rendering the opinion of the Circuit Court of Appeals referred to this phase of the case as follows:

The contention is made, however, that if indeed the prior patents disclose froth processes, the scum which the appellees' process causes to rise to the surface of the water is so different from the froth or scum which arises under the prior art, that it is a new result, and is not anticipated by anything in the prior art. Say counsel for the appellees: "You produce a froth which is not our froth," and again they say that the appellees' froth is "a pure metal froth," while that of the other patents is an "oil froth," and that the appellees' froth consists of air bubbles surrounded by metal armor without any appreciable quantity of oil compared therewith. The evidence in the case, together with the illustration thereof afforded by demonstration of the various processes which were made in the aid of the argument before this court, convince us that the froth in all these processes is the same, with the exception that there is less oil (as there must necessarily be) in the appellees' froth than in the others. The froths are all similar in appearance, they all rise to the surface after the same amount of agitation, they all gather with equal efficiency the same quantity of metal, and they are all removed from the surface in the same way. It is not literally true, of course, that there is no oil in the froth which the appellees produce. If there were no oil in it, there would be no froth. The quantity of oil that has been put into the mixture must necessarily be found in the froth. It would manifestly be a physical impossibility to create a froth consisting only of bubbles of air and the particles of mineral.

The decision of the Appellate Court was:

We hold that to sustain the appellees' patent would be to give to the owners thereof a monopoly of that which others had discovered. What they claim to be the new and useful feature of their invention, as stated by their counsel, is "agitating the mixture to cause the oil's coated mineral to form a froth." As we have seen, that feature was clearly anticipated by the prior art, and when the elements of the appellees' claims are read one by one, it will be found that each step in their process is fully described more than one of the patents of the prior art, with the single exception of the reduced quantity of oil which they use. The patentees of the appellees' patent made a valuable contribution to the art in discovering the smallest quantity of oil which would produce the desired result. In doing so, they opened the course to which all skillful metallurgists would be expected to pursue. They made a series of experiments to determine how small a quantity of oil could be used successfully. They found, as all must find who apply the oil flotation process, that certain oils are adapted to use with certain ores, and that a larger quantity of oil is necessary for one kind of an ore than for another. The appellees admit that for some ores they use four times as much oil as for others. Their discovery that a small fraction of 1 per cent of oil is sufficient to produce flotation of the metalliferous matter cannot, as we have seen, be made by itself or in combination the subject of a patent. The appellees cannot take from others the right to use oil economically.

We are reliably informed that so soon as they learned of the decision of the Supreme Court, the staff of one of the largest mills which is using the agitation froth process raised the amount of oil used to more than 1 per cent and that they still get the froth result with as good concentrates and slightly better recovery. It is found necessary to use less of other reagents, and the grade of oil now used is so cheap that the net profits are practically what they were before. Other companies are adopting the same practice.

Apparently the decision of the Supreme Court was based upon a false assumption as to the facts involved, and the net result of litigation extending over five years' time and costing a fortune is, that after having proceeded within their free rights for two years and a half the companies using the agitation froth process are to be compelled to do what the court previously told them they could not be compelled to do; that is, to use more oil than is necessary to accomplish the result desired.

If, as is demonstrated by this case, the courts cannot be expected to agree with each other with regard to the interpretation of the law and the bearing of facts, it should be apparent that the least possible interference with the progress of industry would come from having all patent cases heard by a single court constituted of judges selected for their technical training and experience and knowledge of the law, this court being a part of the Patent Office and having sole and final jurisdiction in all patent litigation. A certain degree of con-

sistency and uniformity of patent decisions might be expected from such a court.

In the meantime it is probable that in the course of the further litigation arising over this process, the Supreme Court may be convinced that its decision was based upon a false assumption as to the existence of a "critical proportion, a fraction of 1 per cent of oil," and sustain the Court of Appeals' verdict, which was based upon a conception of facts substantiated by the operations of large mills."

Chemical Credits*

By Ellwood Hendrick

The late J. P. Morgan said that if a man had character he would not hesitate to lend him a million dollars without security, but that if he knew him to be deficient in this respect no amount of security would enable the man to borrow money from him. That was a pretty broad statement, but it indicates the nature of credit. Credit is wealth, if you please, but it is of a kind that cannot be obtained ready made. It is, in a sense, an article of barter, because nothing is so easy for a man to trade away as his credit. And yet, it is not merchandise, because the man to whom the original owner trades his credit gets nothing in return but experience. Some kinds of experience may be transformed into credit, but not all. Credit-experience is not exactly a reversible reaction.

Chemical credits are needed, but they are not thoroughly established. Their position is something like that of a St. Louis man, going into a Boston bank to borrow money on Australian securities. Everything is all right except that the transaction does not go through.

The banker does not know the security and he does not know the man. And when we consider how little chemists are known among bankers the problem of the man without a pull is really bewildering when it comes to launching an enterprise.

The business practices of what for want of a better name is called private banking, or sometimes investment banking, have curious psychological sequelæ. Information being the life of the business, it is likely to be secret, and this makes the private banker secretive. On the other hand, among themselves private bankers are gregarious, and they hate to go it alone. It is their habit to invest in series or *en cascade*, so that when two or three leaders subscribe to the underwriting of an enterprise others are likely to follow without much examination. Subscription books close, and there is always the danger that one may be too late. Indeed, there sometimes appears to be as much worry and agony of spirit borne by a banker who invests some money on his own judgment successfully as when he loses the same sum along with the leading houses in the financial district. He dreads solitude in trouble.

The problem, then, in financing an enterprise, is to establish to the satisfaction of one and preferably more than one banker, the merit of the undertaking and the character and ability of the men in charge. Now it is not given to us in youth, as a rule, to select the class at college or the fraternity to which belongs the prospective banker whom we shall want to approach twenty years or more later. It is not given to all of us to live in the same neighborhood as those with funds to invest at the time that we are in the market, and there are a thousand reasons why we may not adjoin or share in opera boxes. The social side of business, however, while still of great weight, is not the sole basis of credit.

The first step in the line of credit is the commercial

*An after-dinner address delivered at the banquet of the American Institute of Chemical Engineers on Jan. 11, 1917.

report, and even here the chemical enterprise is in a bad way. There may be commercial agencies that know how to get the details about an undeveloped or unusual chemical industry and correlate them and get the professional and business records of the men engaged in it, but I have yet to see one. The fact is to make a good, exhaustive report on such an enterprise takes not only time, but chemical knowledge and understanding, and this is just what seems to be lacking. There is, however, no reason why this should not be done. The machinery for gathering full information as to the character and ability of men is at hand in the commercial agencies, and so is that for gleaned information as to the market for special products all over the country. The only thing lacking is chemical direction. Under this there would be gathered and correlated, in addition to the usual information, the very things that it takes a chemical engineer to find out. To the uninformed man location, raw materials, processes and products mean little more than nothing. The chemist can put meaning into them.

How can this be brought about? How can there be established a means for an investor or investors' agent to secure a reliable report on new and changing chemical establishments? How can he get one that he can understand from a source that he knows and on the word of which he is accustomed to determine his credits?

I venture the belief that two or three afternoon sessions of two or three of the right chemical engineers with a couple of sound bankers who have experience in the development rather than the promotion of new enterprises, together with the proper authorities of a mercantile agency that wanted to do this thing, could establish a type of report and lay the foundation of chemical credits. The needful things are: desire by the mercantile agency to do this thing and a willingness on its part to pay for chemical information. I think the chemical engineers and the bankers would gladly contribute time and thought to bring this about.

Coming Meetings and Events

American Paper and Pulp Association, Technical Association, New York, Feb. 6, 7 and 8, 1917.

Joint meeting of New York Section of American Electrochemical Society, American Chemical Society and Society of Chemical Industry, Rumford Hall, Chemists' Club, New York, Feb. 9, 1917.

American Institute of Mining Engineers, annual meeting, New York, Feb. 19-22, 1917.

Program of New York Meeting of American Institute of Mining Engineers

The one hundred and fourteenth meeting of the American Institute of Mining Engineers will be held in New York City, Monday, Feb. 19, to Thursday, Feb. 22, inclusive. A most attractive program has been prepared including the usual technical sessions and entertainment features.

Monday evening will be "College Reunion Night" in the assembly rooms of the Engineering Societies' Building, at 8:30 p. m. Light refreshments and "smokes" will be served. Impromptu addresses will be made with occasional moving pictures of a non-technical character, and other features will be provided to liven things up.

The annual dinner will be held at the Astor on Tuesday evening.

On Wednesday evening a lecture will be given on colored moving pictures and on Thursday an all day

excursion will be made to West Point on a special train. The condensed program and part of the technical program follow:

Special entertainment features will be provided for the ladies as usual.

SUMMARIZED PROGRAM

MONDAY, FEB. 19, 1917

- 9.00 a.m. to 5.00 p.m.—Registration at Institute Headquarters.
- 10.00 a.m.—Simultaneous Sessions on Geology and on Metallurgy.
- 12.30 p.m.—Luncheon at Engineering Societies' Building.
- 2.00 p.m.—Simultaneous Sessions on Petroleum and Gas and on Milling and Smelting.
- 8.00 p.m.—College Reunion Night.

TUESDAY, FEB. 20, 1917

- 10.30 a.m.—Annual Business Meeting followed by Technical Session.
- 12.30 p.m.—Luncheon at Engineering Societies' Building.
- 2.00 p.m.—Simultaneous Sessions on Iron Blast Furnace Practice and on Flotation.
- 6.30 p.m.—Annual Dinner at Hotel Astor, followed by Dancing.

WEDNESDAY, FEB. 21, 1917

- 10.00 a.m.—Session on the Manufacture of Iron and Steel.
- 12.30 p.m.—Luncheon at Engineering Societies' Building.
- 2.00 p.m.—Simultaneous Sessions on Metallography and Heat Treatment of Steel and on Mining Methods.
- 8.00 p.m.—Entertainment and Lecture at Engineering Societies' Building.

THURSDAY, FEB. 22, 1917

- All-day excursion by special train to West Point. (Exhibition horseback riding, inspection of buildings, etc.)

TECHNICAL SESSIONS

MONDAY, FEB. 19, 1917

- 10.00 a.m.—Session on Metallography.
- Grain Growth Phenomena in Metals. By Zay Jeffries.
- On Grain Growth. By Henry M. Howe.
- Recrystallization after Plastic Deformation. By Henry M. Howe.
- Tungsten and Molybdenum Equilibrium Diagram, and System of Crystallization. By Zay Jeffries.
- The System Tungsten-Molybdenum. By Frank Alfred Fahrwald.
- 2.00 p.m.—Session on Milling and Smelting.
- Magnetic Concentration of Low-Grade Magnetic Iron Ore. By S. Norton and S. Le Fevre.
- An Investigation on Rock Crushing Made at McGill University. By John W. Bell.
- Countercurrent Decantation. By Luther B. Eames.
- The Function of Alumina in Slags. By Carl Heinrich.
- A Method for Measuring the Viscosity of Blast-Furnace Slag at High Temperatures. By Alexander L. Field.
- Matte Granulation at Herculaneum, Mo. By S. Paul Lindau and Henry B. Smith.

TUESDAY, FEB. 20, 1917

- 10.00 a.m.—Session on Non-Metallic Minerals. (Following Annual Business Meeting.)
- A Study of the Silica Refractories. By J. Spotts McDowell.
- The Genesis of Asbestos and Asbestiform Minerals. By Stephen Taber.
- The Conservation of Phosphate Rock in the United States. By W. C. Phalen.
- 2.00 p.m.—Session on Iron Blast-Furnace Practice
- Dry-Hot versus Cold-Wet Blast-Furnace Gas. By Linn Bradley, H. D. Egbert and W. W. Strong.
- Some Suggestions Regarding Construction of Hot Blast Stoves. By Linn Bradley, H. D. Egbert and W. W. Strong.
- Calculations with Reference to the Use of Carbon in Modern American Blast Furnaces. By Henry Phelps Howland.
- Potash as a By-Product from the Blast Furnace. By R. J. Wysor.
- 2.00 p. m.—Session on Flotation
- Notes on Flotation—1916. By J. M. Callow.

WEDNESDAY, FEB. 21, 1917

- 10.00 a.m.—Session on the Manufacture of Iron and Steel.
- The Seasoning of Castings. By Richard Moldenke.
- Significance of Manganese in American Steel Metallurgy. By F. H. Willcox.
- Roll Scale as a Factor in the Bessemer Process. By A. Patton and F. N. Speller.

Temperature Measurements in Bessemer and Open-hearth Practice. By George K. Burgess.

The Manufacture of Weldless Steel Tires for Locomotives and Car Wheels. By Guillaume Aertsen.

2.00 p. m.—Session on Metallography and Heat-Treatment of Steel

Notes on the Heat Treatment of High-Speed Steel Tools. By A. E. Bellis and T. W. Hardy.

Effect of Time in Reheating Hardened Steel Below the Critical Range. By C. R. Hayward and S. S. Raymond.

Erosion of Guns—The Hardening of the Surface. By Henry Fay.

The Effect of Sulphur on Low-Carbon Steel. By Carle R. Hayward.

A Method for Distinguishing Sulphides from Oxides in the Metallography of Steel. By George F. Comstock.

Symposium on the Smelter Smoke and Fume Problem

Three interesting papers on the smoke and fume problem were presented on Friday evening, Jan. 26, at a joint meeting of the New York Sections of the American Electrochemical Society and American Institute of Mining Engineers, held at the Machinery Club.

Mr. LIGON JOHNSON, consulting attorney for the International Nickel Company, and the American Smelting & Refining Company, was the first speaker. He outlined in a very interesting manner the whole legal history of the smoke and fume problem, and then explained the large amount of experimental work done by the American Smelting & Refining at Salt Lake City and other points, in determining the actual extent of the harm done by waste smelter gases to plant life. It was found that all the harm done to plant life was due to SO_2 , or mixtures of SO_2 and SO_3 , when the plants are in leaf. The visible fume was found to have little effect, it being the invisible fume which does the damage. High stacks and hot exit gases are recommended for visual clearance.

Mr. W. W. STRONG gave a very interesting talk on "Theoretical Aspects of Electrical Precipitation," explaining the corona discharge, electrical wind, and showing just how the precipitation is accomplished. His talk was illustrated with some interesting slides.

Mr. LINN BRADLEY discussed the latest developments in the use of the Cottrell process. One of the most interesting points brought out by him was the necessity of having conditions in all the tubes the same, i.e., regarding each tube in a several tube unit, as a single tube and keeping the conditions in each tube the same as found successful in preliminary experiments, which are made in a single tube. Mr. Bradley concluded his part of the program with some interesting moving pictures of recent Cottrell installations, in connection with brass melting, slate grinding, and smelting.

Both the dinner and the technical session were well attended, there being about 200 present.

Current News and Notes

Local Refining of Metals Planned in Canada.—It is expected that a government bill will be introduced at the approaching session of Parliament in Ottawa, which will provide aid by bounty or tariff for the increased refining of lead, copper and zinc in Canada.

Rubber Club Holds Annual Meeting.—The annual meeting and banquet of the Rubber Club of America was held at the Waldorf-Astoria, New York City, on Monday, January 8. Divisional meetings and business meetings were held during the day and the banquet at 6:30 p. m. The principal speakers at the

banquet were Ex-President William H. Taft, Colonel Samuel P. Colt, president of the United States Rubber Company, and Samuel McRoberts, vice-president of the National City Bank, the latter substituting for Frank A. Vanderlip, president of the National City Bank. It had been planned to have a symposium on crude rubber to take up the question of insuring a supply of crude rubber to the country at all times, but there were so many other functions that this had to be postponed to a later date.

Foreign Trade Convention.—The Fourth National Foreign Trade Convention of the National Foreign Trade Council will be held at the William Penn Hotel, Pittsburgh, Pa., January 25, 26 and 27, 1917. Many important questions will be discussed such as the following: Conditions in foreign markets after the war, and the measures necessary to safeguard American foreign trade, as well as the foreign trade aspect of the American tariff system; co-operation in foreign trade development; the American merchant marine; foreign investment of American capital as an aid to oversea commerce, and problems of the smaller manufacturer and merchant.

Course for Prospectors at University of Utah.—The School of Mines and Engineering of the University of Utah, Salt Lake City, has established a course for prospectors, which will be given this winter during the four weeks from Jan. 8 to Feb. 3. The course will cover the fundamentals of geology, mineralogy, mining and the metallurgical treatment of ores. Professor Robert S. Lewis is in charge of the mining department.

Meeting of Mining and Metallurgical Society.—The annual meeting of the Mining and Metallurgical Society of America was held at the Engineers' Club, Jan. 9. The officers elected for the coming year are W. R. Ingalls, president; Waldemar Lindgren, vice-president; Louis D. Huntoon, secretary-treasurer. The annual gold medal of the Society was awarded to E. P. Mathewson for his achievements in non-ferrous metallurgy. Action was taken endorsing Belgian Kiddies, Ltd., and David H. Browne spoke on Mr. Hoover's work and urged greater support for this movement. Mr. George S. Rice of the Bureau of Mines spoke on the Joseph A. Holmes Safety Association and Mr. H. W. DuBois showed some interesting mining pictures of Alaska.

The Colorado Section of the A. I. M. E. held its annual meeting on January 15, 1917, at the University Club in Denver. The following officers were elected for the coming year: Chairman, Chas. Loughridge; vice-chairman, George M. Taylor; directors, Fred A. Bostwick and P. M. McHugh; secretary and treasurer, Fred Carroll. The meeting was non-scientific; the program involved the following numbers of note: Address by L. D. Ricketts, president of the A. I. M. E., over long-distance telephone; "Flotation Exposed and Explained," by H. C. Parmelee, and "The Latest Practice in Cyanide Milling," by T. B. Stearns. Each member present at the banquet had a telephone at his place so as to be sure to hear Dr. Ricketts' voice. Dr. Ricketts' proxy was Mr. Stearns, located in an adjoining room. Most of the crowd were fooled. Mr. Parmelee showed, by very elaborate tests, the value of the flotation process. The experiments consisted in proving once and for all that cork will sink and galena will float. To demonstrate the latest practice in cyaniding, Mr. Stearns made use of the celebrated Metallurgical Cow. The meeting was a success from start to finish and all the members left on their homeward trip thoroughly convinced that both flotation and the new cyanide practice were here to stay.

The Calculation of Lead Blast Furnace Charges—II.

By Boyd Dudley, Jr.

(Concluded from page 93)

PROBLEM II.

Materials of compositions shown in the following table are to be smelted in the lead blast furnace.

Material	H ₂ O, Per Cent	Pb, Per Cent	Cu, Per Cent	SiO ₂ , Per Cent	Fe, Per Cent	Mn, CaO, Per Cent	MgO, S, Per Cent
D. and L. sinter	0.0	37.20	1.35	17.3	18.4	2.1	10.3
Silicious mixture	4.7	5.35	0.65	50.4	10.2	1.1	5.8
Pyrite cinder	2.3	0.0	0.38	10.6	58.2	0.0	2.3
Lime stone	4.2	0.0	0.0	6.5	5.3	0.0	43.2
Coke	0.0	0.0	0.0	5.2	1.2	0.0	1.1

Conditions and assumptions: The supplies of D. and L. (Dwight and Lloyd) sinter and of the silicious ore mixture are such that these two materials must be charged in equal quantities to the furnace. With them enough pyrite cinder, limestone, and coke are to be smelted to conform to the following assumed conditions.

It is desired to produce a slag that will contain silica 32 per cent, ferrous oxide 38 per cent, and lime 20 per cent, leaving 10 per cent to be formed by the minor constituents.

The amount of coke is to be 14 per cent of the charge.

Assume that 20 per cent of the sulphur charged to the furnace will escape with the gases, that the slag produced will analyze 1.0 per cent of sulphur, and that the remaining sulphur will form matte containing 23.0 per cent of sulphur and 46.0 per cent of iron. Assume also that all of the copper of the charge will enter the matte, and that sulphur, iron, copper, and lead will constitute 90.0 per cent of the matte as it is produced.

Assume that 4.0 per cent of the lead on the charge will be volatilized and escape with the furnace gases, that the slag will analyze 0.70 per cent of lead, and that the bullion produced will contain 97.0 per cent of lead.

Required: a—Determining the amount of pyrite cinder, of limestone, and of coke to be charged with 1000 lb. of D. and L. sinter and 1000 lb. of the silicious mixture, dry weights being considered.

b—Calculate the wet weight of each material to be employed in making an 8000 lb. charge, exclusive of the coke. What amount of coke should accompany such a charge?

c—What will be the matte fall, *i. e.*, what per cent will the matte be of the charge that produces it? Calculate the approximate composition of the matte.

d—What will be the bullion fall, *i. e.*, what per cent of the charge is the bullion that it produces? Compare this with the per cent of lead on the charge.

Notes: In order to secure uniformity it is customary to make chemical analyses on samples that have been dried at a constant temperature, say 105° C. The loss in weight at this temperature is generally reported as moisture, and the amounts of the determined constituents are calculated as percentages of the dry weight. The moisture, on the other hand, is calculated as a per cent of the wet weight. The reason for this procedure should be evident. When the materials that enter into a furnace charge are weighed, the moisture that each contains has to be taken into account, and this can best be done by deducting the determined percentage of moisture in terms of the wet weight. There is thus left the net or dry weight, to which the various percentages of the chemical analysis apply.

The coke analysis given in the table is based upon the air dried weight, which is the one generally employed unless the coke is shipped or stored under conditions that may expose it to excessive wetting.

It will be observed that among the chemical constituents specified in the table there are manganese and magnesia in addition to those considered in the previous problem. The occurrence of these is a quite common thing, and they are generally taken into account in the following manner:

The atomic weight of manganese is 54.93, while that of iron is 55.84. Furthermore, the chemical characteristics of the two elements have much in common. Therefore, when manganese is present in not too great amounts, it may be considered as having the same chemical effect as iron, and the amount of one may be added directly to the amount of the other. It is also customary to consider the atomic weight of iron or of combined iron and manganese as 56 rather than to employ the more exact figure 55.84. This is a justifiable approximation and produces a simple ratio between iron and ferrous oxide,

$$\text{Fe} : \text{FeO} = 56 : 72 = 7 : 9.$$

This relationship was employed in the previous problem and will be employed in this and the succeeding one.

In a similar manner magnesia may be considered as having much the same effect as lime. But owing to the difference between the molecular weights of these compounds, the magnesia is the more effective of the two as a basic slag constituent, and if, for the sake of simplicity, it is desired to add magnesia to lime and to consider both oxides as lime, the magnesia must be given its proper lime value. This is done on the assumption that a molecule of magnesia has the same chemical effect in the slag as does a molecule of lime. Hence, the molecular weight of magnesia being 40 and that of lime being 56, one unit of magnesia is equivalent to $56 \div 40 = 1.4$ units of lime.

While the calculation of magnesia as lime according to the above ratio is a justifiable short cut, it introduces an alteration of the original set of assumed conditions that should be pointed out. It was assumed that silica, ferrous oxide, and lime would together constitute 90 per cent of the slag produced, the remainder being composed of alumina, zinc, sulphur, lead, etc. But now it is proposed to consider each unit weight of magnesia present as 1.4 units of lime, and still to calculate the silica, ferrous oxide, and lime thus determined as aggregating 90 per cent of the slag. It is evident that percentages and molecular weights are here being combined in a manner that is theoretically incorrect. But unless the amounts of magnesia in the charged materials are high, the error thus introduced is of little practical importance, and the calculations are greatly simplified by this procedure.

Solution: As before, it is well to calculate the slag ratios at the outset, taking a unit weight of silica as the standard. For each pound of silica in the slag there will be other constituents as follows:

$$\text{Iron} = \frac{38\% \text{ FeO}}{32\% \text{ SiO}_2} \times \frac{7}{9} \text{ (ratio Fe to FeO)} = 0.924 \text{ lb.}$$

$$\text{Lime} = \frac{20\% \text{ CaO}}{32\% \text{ SiO}_2} = 0.625 \text{ lb.}$$

$$\text{Sulphur} = \frac{1\% \text{ S}}{32\% \text{ SiO}_2} = 1/32 \text{ lb.}$$

That is, the amounts of silica, iron, lime, and sulphur in the slag should be present in accordance with the relation:

$$\text{Silica} : \text{Iron} : \text{Lime} : \text{Sulphur} = 1.00 : 0.924 : 0.625 : 1/32.$$

Before proceeding to draw up a charge sheet the analyses of the different materials can be simplified according to the notes outlined above. Thus in the D. and L. sinter:

18.4% Fe + 2.1% Mn = 20.5% Fe, and
 10.3% CaO + (1.2% MgO $\times$ 1.4) = 12.0% CaO.
 In the silicious ore mixture:
 10.2% Fe + 1.1% Mn = 11.3% Fe.
 In the limestone:
 43.2% CaO + (3.2% MgO $\times$ 1.4) = 47.7% CaO.

The various materials with their simplified analyses may now be entered on a charge sheet, which may conveniently have the following form. In this case the lead and copper figures may be omitted for the present, and since the D. and L. sinter and the silicious mixture are to be smelted in equal quantities, 1000 lb. of each may be entered at once on the sheet. This has been done in lines *a* and *b*, and the amounts of the constituents thus provided have been calculated and entered in their proper places.

Material	Dry Wt.	Silica		Iron		Lime		Sulphur	
		Per Cent	Wt.	Per Cent	Wt.	Per Cent	Wt.	Per Cent	Wt.
<i>a</i> —D. & L. sint.	1,000	17.3	173	20.5	205	12.0	120	4.37	43.7
<i>b</i> —Silic. mixtr.	1,000	50.4	504	11.3	113	5.8	58	5.28	52.8
<i>c</i> —Tt's <i>a</i> & <i>b</i>	2,000			677	318		178		96.5
<i>d</i> —Pyrite cind.	950	10.6	101	58.2	553	2.3	22	1.87	17.8
<i>e</i> —Limestone.	680	6.5	44	5.3	36	47.7	324	0.43	2.9
<i>f</i> —Coke	508	5.2	26	1.2	6	1.1	6	1.24	6.2

<i>h</i> —Second trial totals			853		933		534		124.0

The amounts of silica, iron, lime, and sulphur in the D. and L. sinter and in the silicious mixture may now be added. The respective totals have been entered in line *c* of the charge sheet. The problem has now resolved itself into a very simple form. It is only necessary to provide pyrite cinder, limestone, and coke in proper quantities for the amounts of various constituents shown in line *c* of the sheet. The method of making estimates of these quantities and of finally balancing the charge is as follows:

To estimate the amount of pyrite cinder, consider the totals of line *c*. Of the 96.5 lb. of sulphur present 80 per cent will remain in the furnace and enter the matte and slag. The exact amount of this that will ultimately enter the slag is a matter of speculation. But it is seen that the silica of line *c* amounts to 677 lb., and according to the assumed slag ratio each unit of silica will be accompanied in the slag by 1/32 unit of sulphur. Therefore, considering the material of line *c* alone it is seen that:

Sulphur to matte and slag = 96.5 lb. $\times$ 0.80 =	77.2 lb.
Sulphur to slag = 677 lb. $\div$ 32 =	21.2 lb.
Sulphur to matte after deducting gas and slag losses =	56.0 lb.
Iron present for slag and matte =	318 lb.
Iron required for matte = 56 lb. $\times$ 2 =	112 lb.
Iron available for slag =	206 lb.
Silica present for slag =	677 lb.
Silica provided with iron = 206 lb. $\div$ 0.924 =	223 lb.
Silica of line <i>c</i> in excess of iron =	454 lb.

It is evident that there is 454 lb. of silica in line *c* that will require iron from an external source. Now consider the analysis of the pyrite cinder. The 10.6 per cent of silica present therein will require approximately 10 per cent of iron in forming slag. There is also present 1.87 per cent of sulphur, a part of which will require iron in forming matte. A quick mental estimate shows that the amount of iron so required will not be less than 2 per cent. Hence approximately 12 per cent of the iron of the pyrite cinder will be required by the silica and sulphur of that material. There re-

mains practically 46 per cent of available iron, which may be employed in supplying the deficit of iron in line *c*.

The pyrite cinder required to furnish free iron for 454 lb of silica is

$$454 \text{ lb.} \times 0.924 = 913 \text{ lb.} \\ 0.46$$

This amount of pyrite cinder would provide the necessary iron for the materials of lines *c* and *d*, but these materials are not to be smelted alone. There must still be added certain amounts of limestone and coke, both of which contain silica and also sulphur. Inspection of the limestone analysis shows that iron and silica are fairly well balanced in this material, although there is a small amount of sulphur, which the iron may not fully cover. On the other hand, the coke is seen to contain a large excess of silica over iron and also to contain considerable sulphur. It is therefore clear that the 913 lb. of cinder estimated above will prove insufficient to provide iron for the entire charge. The amount to be added to 913 lb. of pyrite cinder in order to allow iron for the silica and sulphur of the coke might be estimated by a process similar to that which has been followed up to the present. But in general such an estimate will consume more time than will an arbitrary addition to the estimated amount and a trial of the charge to determine whether or not it is properly balanced. For instance, suppose that in this case 950 lb. of pyrite cinder is entered in line *d*. Understand, this is a purely arbitrary increase over the amount first estimated. It may be too much or too little. Judgment and previous experience may be well used in this case, although they are not in any way essential. Calculate and enter the constituents of 950 lb. of pyrite cinder in their respective spaces in line *d*.

Now proceed to estimate the amount of limestone as follows. In lines *c* and *d* there are present 778 lb. of silica and 200 lb. of lime

Lime requirement of silica = 778 lb. $\times$ 0.625 =	486 lb.
Lime already present =	200 lb.
Lime required to supply deficit in lines <i>c</i> and <i>d</i> =	286 lb.

Considering the analysis of the limestone, 6.5 per cent of silica will require $6.5 \times 0.625 = 4.1$ per cent of lime. This leaves $47.7 - 4.1 = 43.6$ per cent of lime in excess of that required by the silica of the limestone itself, *i.e.*, 43.6 per cent of available lime. The amount of limestone required to provide 286 lb of available lime is therefore

$$\frac{286 \text{ lb.}}{0.436} = 656 \text{ lb.}$$

This will provide sufficient lime for everything on the charge except the coke, and the analysis of this material shows that there is a large excess of silica in it above the lime that it contains. Here again an estimate of the amount of limestone to add for the purpose of providing lime for the coke could be attempted, but suppose 680 lb. of limestone is entered for a first trial. This is an arbitrary increase to be sure, but it will not be far wrong and will probably be productive of a saving of time. Calculate and enter in line *e* the amounts of constituents in 680 lb. of limestone.

The coke may now be calculated and entered. The charge as it now stands consists of 1000 lb. of D. and L. sinter; 1000 lb. of silicious mixture; 950 lb. of pyrite cinder, and 680 lb. of limestone, making a total of 3630 lb. The amount of coke to be employed is 14 per cent of the charge. Hence

$$\text{Coke} = 3630 \text{ lb.} \times 0.14 = 508 \text{ lb.}$$

Enter this with its constituents in their proper places in line *f*.

The entire charge as thus estimated may now be

tested to determine whether or not the materials are present in proper proportions. The method of performing this operation is as follows.

Add the amounts of silica, iron, lime, and sulphur present on the charge, and enter the totals in line *g* of the sheet. Considering the figures therein,

Sulphur to matte and slag = $123.4 \text{ lb.} \times 0.80 =$	98.8 lb.
Sulphur to slag = $848 \text{ lb.} \div 32 =$	26.5 lb.
Sulphur to matte =	72.3 lb.
Iron on charge =	913 lb.
Iron to matte = $72.3 \text{ lb.} \times 2 =$	145 lb.
Iron to slag =	768 lb.
Iron required by silica = $848 \text{ lb.} \times 0.924 =$	783 lb.
Deficit of iron =	15 lb.
Lime on charge =	530 lb.
Lime required by silica = $848 \text{ lb.} \times 0.625 =$	530 lb.

It is thus seen that the charge as first estimated is properly balanced with respect to lime but lacks iron to the extent of 15 lb. This will necessitate an addition to the pyrite cinder, the amount of which will be approximately

15 lb. deficit of iron

0.46 available iron in cinder = 33 lb.

For convenience this may be increased to 35 lb., making the second estimate of pyrite cinder $950 \text{ lb.} + 35 \text{ lb.} = 985 \text{ lb.}$

In order to preserve a clean and neat sheet and at the same time to have the result of each trial in evidence it is better not to erase the first estimates, but to extend the charge sheet downward as has been done. In line *h* the totals of lines *a* and *b* have again been entered. In line *i* the new amount of pyrite cinder is entered, and the amounts of its constituents are computed and entered in their proper places.

Now for the limestone, in the first charge the lime was seen to be balanced to the nearest pound, but the addition of 35 lb. to the pyrite cinder will add silica to the charge in excess of the lime added, and this balance of lime will be disturbed. Hence, for a second trial the limestone should be increased as well as the pyrite cinder. Inspection of the cinder analysis with reference to silica and lime shows that an increase of 35 lb. in this material will introduce about 2 lb. of silica in excess of lime, and this may be corrected by adding 5 lb. to the limestone. Therefore, for a second trial the limestone should be increased from 680 lb. to 685 lb.

These additions to the charge will necessitate a corresponding increase in the coke, the new weight being $(2000 + 985 + 685) \text{ lb.} \times 0.14$

$$= 3770 \text{ lb.} \times 0.14 = 515 \text{ lb.}$$

Entering the 685 lb. of limestone in line *j* and 515 lb. of coke in line *k* yields the second completed charge, which can be tested as before.

Considering the totals entered in line *l*,

Sulphur to matte and slag = $124 \text{ lb.} \times 0.80 =$	99.2 lb.
Sulphur to slag = $853 \text{ lb.} \div 32 =$	26.6 lb.
Sulphur to slag =	72.6 lb.
Iron on charge for matte and slag =	933 lb.
Iron required by matte = $72.6 \text{ lb.} \times 2 =$	145 lb.
Iron for slag =	788 lb.
Iron required by silica = $853 \text{ lb.} \times 0.924 =$	788 lb.
Lime on charge =	534 lb.
Lime required by silica = $853 \text{ lb.} \times 0.625 =$	533 lb.
Excess of lime on charge over requirement =	1 lb.

This charge may be considered as satisfactory, and the finished charge will consist of D. and L. sinter 1000 lb., silicious ore mixture 1000 lb., pyrite cinder 985 lb., limestone 685 lb., and coke 515 lb. These are dry or net weights, and in those cases where the material contains a known amount of moisture the proper allowance must be made.

Requirement *b* in the statement of the problem asks for the wet weights of these materials to be used in an 8000 lb. charge. First let the wet weights of materials entering the charge as already determined be calculated, bearing in mind that the percentages of moisture specified in the analyses are based upon the wet weights. Hence

Wet weight =

$$\text{Dry weight} \times \frac{100}{100 - \text{per cent moisture on dry weight}}$$

The actual or wet weights required to form the charge as calculated above are as follows:

Material	Dry Weight	Wet Weight
D. and L. sinter	1,000 lb.	1,000 lb.
Silicious mixture	$1,000 \text{ lb.} \times \frac{100}{100 - 4.7} =$	1,050 lb.
Pyrite cinder	$985 \text{ lb.} \times \frac{100}{100 - 2.3} =$	1,010 lb.
Limestone	$685 \text{ lb.} \times \frac{100}{100 - 4.2} =$	715 lb.
Coke	515 lb.	515 lb.

The total of the wet weights exclusive of the coke is 3775 lb. and in order to determine the amount of each material to use in an 800 lb. charge it is simply necessary to multiply each by the factor

$$\frac{8000}{3775} = 2.12$$

Thus

D. and L. sinter	$= 1,000 \text{ lb.} \times 2.12 =$	2,120 lb.
Silicious mixture	$= 1,050 \text{ lb.} \times 2.12 =$	2,225 lb.
Pyrite cinder	$= 1,010 \text{ lb.} \times 2.12 =$	2,140 lb.
Limestone	$= 715 \text{ lb.} \times 2.12 =$	1,515 lb.
Total		8,000 lb.
Coke = 14 per cent of dry charge = $515 \text{ lb.} \times 2.12 =$		1,090 lb.

Requirement *c* in the statement of the problem asks for a calculation of the matte fall and the approximate composition of the matte, it being assumed that all of the copper on the charge will enter the matte, and that this together with iron, lead and sulphur will constitute 90 per cent of the matte produced. It is also assumed that the matte as produced will contain 23 per cent of sulphur and 46 per cent of iron.

For convenience in making these calculations let the last set of figures entered on the charge sheet be considered, i.e., the finished charge as it was determined in terms of dry weights. In balancing the charge the last time it was found that 72.6 lb. of sulphur would enter the matte. If this constitutes 23.0 per cent of the matte produced, the weight of matte from this charge will be

$$\frac{72.6 \text{ lb.}}{0.230} = 316 \text{ lb.,}$$

and the matte fall will be

$$\begin{aligned} \text{Weight of matte} \times 100 &= \frac{316 \times 100}{3670} \\ \text{Weight of charge producing matte} &= 8.61 \text{ per cent.} \end{aligned}$$

Now the amount of copper on the charge is as follows:

1,000 lb. D. and L. sinter $\times 0.0135 =$	13.5 lb.
1,000 lb. silicious ore mixtures $\times 0.0065 =$	6.5 lb.
985 lb. pyrite cinder $\times 0.0038 =$	3.7 lb.
Total =	23.7 lb.

Assuming that all of this copper will enter the matte, the matte will contain

$$\frac{23.7 \times 100}{316} = 7.5 \text{ per cent copper.}$$

If sulphur, copper, iron, and lead constitute 90.0 per cent of the matte, then the lead will be

$$90.0 - (23.0 + 46.0 + 7.5) = 90.0 - 76.5 = 13.5 \text{ per cent.}$$

So the matte as thus calculated will consist of

	Per Cent	Weight
Sulphur =	23.0 = 316 lb. $\times$ 0.230 =	72.6 lb.
Iron =	46.0 = 316 lb. $\times$ 0.460 =	145 lb.
Copper =	7.5 = 316 lb. $\times$ 0.075 =	23.7 lb.
Lead =	13.5 = 316 lb. $\times$ 0.135 =	42.6 lb.
Miscel. =	10.0 = 316 lb. $\times$ 0.100 =	31.6 lb.

Requirement *d* in the statement asks for a calculation of the bullion fall and a comparison of this with the per cent of lead on the charge. It is assumed that 4.0 per cent of the lead charged to the furnace is lost as dust and fume, that the slag will contain 0.70 per cent of lead, and that the base bullion produced will contain 97.0 per cent of lead.

The amount of lead on the charge is

1,000 lb. D. and L. sinter $\times$ 0.372 =	372 lb.
1,000 lb. silicious ore mixture $\times$ 0.0535 =	53.5 lb.
Total =	425.5 lb.

Hence the lead on the charge is

$$\frac{425.5 \times 100}{3670} = 11.6 \text{ per cent.}$$

The bullion fall is calculated by deducting the various amounts of lead that do not enter the bullion from that present. Thus

Lead lost to stack as dust and fume =	425.5 $\times$ 0.040 =	17.0 lb.
Lead entering matte =		42.6 lb.
Lead lost in slag = silica $\times$ 0.70 =	853 lb. $\times$ 0.0218 =	18.6 lb.
		78.2 lb.
Lead present on charge =		425.5 lb.
Lead to stack, matte and slag =		78.2 lb.
Lead entering bullion =		347.3 lb.

If this lead constitutes 97.0 per cent of the bullion produced, then the amount of bullion from this charge is

$$\frac{347.3 \text{ lb.}}{0.970} = 358 \text{ lb.,}$$

and the bullion fall is

$$\frac{358 \times 100}{3670} = 9.75 \text{ per cent.}$$

In concluding this problem it should be remarked that the calculation of matte composition in advance is not, as a rule, a very practicable or necessary operation. It is given here, together with the bullion calculation, more as an exercise to bring before the student certain facts as to matte and bullion constitution, lead losses, etc., than for any other reason. It is true, however, that the converse of such calculations have frequent application, *i.e.*, the matte, slag, and bullion analyses with their respective production figures are employed in calculations to determine and check the metal losses incidental to the operation. This point will be illustrated in the solution of the next problem.

In the problem just completed the calculations involved, when moisture, manganese, and magnesia are taken into consideration, have been illustrated. For this reason these factors will not be introduced again, and analyses that have presumably been already simplified and are stated in terms of dry weights will be employed hereafter.

PROBLEM III

Materials of compositions shown in the following table are to be smelted in the lead blast furnace.

Material	Lead, Per Cent	Silica, Per Cent	Iron, Per Cent	Lime, Per Cent	Sulphur, Per Cent
D. and L. sinter	39.50	17.5	20.6	12.5	4.25
Silicious ore	12.30	50.1	10.7	2.3	5.33
Iron ore	0.0	12.6	55.3	1.7	1.94
Limestone	0.0	7.5	4.2	46.8	0.0
Coke	0.0	5.2	1.2	1.1	1.32

Conditions and assumptions.—It is desired to have

12.0 per cent of lead on the finished charge, *i.e.*, the two lead bearing materials are to be so proportioned that 12.0 per cent of the charge including iron ore and limestone, but not including coke, will consist of lead.

It is desired to produce a slag that will contain silica 34 per cent, ferrous oxide 28 per cent, and lime 28 per cent, leaving 10 per cent to be formed by the minor constituents.

The amount of coke is to be 14 per cent of the charge.

Assume that 20 per cent of the sulphur charged to the furnace will escape with the gases, that the slag produced will analyze 1.0 per cent of sulphur, and that the remaining sulphur will form matte containing 23.0 per cent of sulphur and 46.0 per cent of iron.

Assume that when this furnace charge as calculated is actually smelted the matte fall is found to agree with the calculated figure, and an analysis of the matte shows a 12.5 per cent lead content.

Assume that the amount of bullion produced from the charge is 10.3 per cent, and that it shows on analysis 97.0 per cent of lead.

Assume that the slag as produced contains 0.68 per cent of lead.

Required.—(a) Determine the amounts of silicious ore, iron ore, limestone, and coke to be smelted with 1000 lb. of the D. and L. sinter in order to comply with the above outlined conditions.

(b) Calculate the distribution of the lead on the charge among the various products formed, bullion, matte, slag, and flue loss.

Notes.—The condition imposed in this case, that the charge shall contain a definite amount of lead, is one that is frequently encountered in districts where silver-lead smelters have offerings of considerable quantities of low-lead, silicious ores. In such cases ores that are rich in lead are valuable not only for the metal itself, but the lead in such materials may serve as a collector for silver and gold occurring in ores that contain little or no lead. In other words, the ore that is rich in lead is diluted with such a quantity of ore that is low in lead as it will take, and still maintain a given quantity of lead on the furnace charge.

In this case it is required that 12.0 per cent of lead be present, although this does not represent the minimum that might be successfully employed.

There are several methods whereby this problem might be solved. One of the most obvious, and the one that will be here employed, consists of making two separate calculations, the first involving 1000 lb. of the D. and L. sinter with the necessary fluxes and coke, the second involving a like amount of the silicious ore with its necessary fluxes and coke. Thus two charges will be calculated and subsequently combined in the manner required to make lead 12.0 per cent of the final charge.

Solution.—Again the logical starting point is the calculation of the slag ratios, and again a unit weight of silica will be taken as the standard. In a slag of the desired composition the amounts of other constituents present with each pound of silica will be:

Iron =	$\frac{28\% \text{ FeO}}{34\% \text{ SiO}_2} \times \frac{7}{9}$ (ratio of Fe to FeO) =	0.640 lb.
Lime =	$\frac{28\% \text{ CaO}}{34\% \text{ SiO}_2} =$	0.824 lb.
Sulphur =	$\frac{1.0\% \text{ S}}{34\% \text{ SiO}_2} =$	1/34 lb.

A charge sheet may now be drawn up according to the following form. The first charge to be calculated involving 1000 lb. of D. and L. sinter will hereafter be designated as Charge A, while the second one involving 1000 lb. of the silicious ore will be designated as Charge B.

CHARGE SHEET, PROBLEM III

CHARGE A.

	Material	Dry Weight	Silica		Iron		Lime		Sulphur	
			Per Cent	Wt.	Per Cent	Wt.	Per Cent	Wt.	Per Cent	Wt.
a	D. & L. sint.	1,000	17.5	175	20.6	206	12.5	125	4.25	42.5
b	Silicious ore	115	50.1	58	10.7	12	2.3	3	5.38	6.2
c	Limestone	170	7.5	12	4.2	7	46.3	80	0.0	0.0
d	Coke	180	5.2	9	1.2	2	1.1	2	1.32	2.4
e	First trial totals			354		227		210		51.1

g	Silicious ore	105		53		11		2		5.7
h	Limestone	160		11		7		75		2.3
i	Coke	177		9		2		2		
j	Second trial totals			248		226		204		50.5

CHARGE B.

	Material	Dry Weight	Silica		Iron		Lime		Sulphur	
			Per Cent	Wt.	Per Cent	Wt.	Per Cent	Wt.	Per Cent	Wt.
k	Silicious ore	1,000	50.1	501	10.7	107	2.3	23	5.38	53.8
l	Iron ore	640	12.6	82	55.3	354	1.7	11	1.9	12.6
m	Limestone	1,125	7.5	83	4.2	47	46.8	526	0.0	0.0
n	Coke	388	5.2	20	1.2	5	1.1	4	1.32	5.1
o	First trial totals			686		518		564		71.5
p	Silicious ore	1,000		501		107		23		53.8
q	Iron ore	640		81		354		11		12.4
r	Limestone	1,125		83		47		526		0.0
s	Coke	387		20		5		4		5.1
t	Second trial totals			685		513		564		71.3

In calculating Charge A the first thing to enter is 1000 lb. of the D. and L. sinter, together with the amounts of its constituents, in line *a*. Now before entering any further analyses it will be well to consider the figures in line *a* and find out what further materials are needed to complete the charge. From the figures in line *a*,

Sulphur to matte and slag = 42.5 lb. $\times$ 0.80 =	34.0 lb.
Sulphur to slag with silica = 175 lb. $\div$ 34 =	5.2 lb.
Sulphur to matte after deducting gas and slag losses =	28.8 lb.
Iron present for matte and slag =	206 lb.
Iron to matte with sulphur = 28.8 lb. $\times$ 2 =	58 lb.
Iron available for slag =	148 lb.
Iron required by silica = 175 lb. $\times$ 0.64 =	112 lb.
Iron excess over silica in 1,000 lb. D. and L. =	36 lb.

This is a new situation. The principal material in Charge A has an excess of iron over that required by its silica and sulphur to form slag and matter. Therefore iron ore will not be needed on this charge, but there is need for a silicious material. The logical thing to use under these circumstances is some of the silicious ore that is to be smelted. The next question is, how much?

In order to estimate the amount of the silicious ore that will be required by the D. and L. sinter it is necessary to consider the amounts of iron, silica, and sulphur in the former. The analysis shows

Sulphur to matte and slag = 5.38 per cent $\times$ 0.80 =	4.30 per cent
Sulphur to slag = 50.1 per cent $\div$ 34 =	1.47 per cent
Sulphur to matte =	2.83 per cent
Iron present =	10.7 per cent
Iron to matte = 2.83 per cent $\times$ 2 =	5.7 per cent
Iron for slag =	5.0 per cent
Silica present =	50.1 per cent
Silica to slag with iron = 5.0 per cent $\div$ 0.640 =	7.8 per cent
Silica in excess of iron =	42.3 per cent

It has been shown that 1000 lb. of D. and L. sinter contains 36 lb. of iron in excess of silica, and if silica for this iron is to be supplied from the silicious ore, which has 42.3 per cent of silica in excess of iron, then the amount of silicious ore required will be

$$\frac{36 \text{ lb. of iron}}{42.3} \times 100 = 133 \text{ lb.}$$

This then would provide the correct amount of silica for the D. and L. sinter, but the analyses of the limestone and coke show that both of these materials contain silica in excess of iron. Therefore 133 lb. of the

silicious ore would provide an excess of silica on the finished charge. For the first trial a smaller amount should be used, say 115 lb. Enter it in line *b* of the charge sheet, entering also the amounts of the constituents of this material in their proper places.

An estimate of the limestone may now be made, taking into account the silica and lime shown in lines *a* and *b*.

Lime required by 233 lb. silica = 233 lb. $\times$ 0.824 =	192 lb.
Lime present in lines <i>a</i> and <i>b</i> =	128 lb.
Lime to be supplied =	64 lb.

In the limestone the 7.5 per cent of silica will require $7.5 \times 0.824 = 6.2$ per cent of the lime, and this leaves $46.8 - 6.2 = 40.6$ per cent of lime in excess of the silica. The amount of limestone required to provide 64 lb. of available lime will therefore be

$$\frac{64 \text{ lb.}}{0.406} = 158 \text{ lb.}$$

But this will be insufficient for the entire charge, because the coke is not included in making this estimate, and the coke analysis shows an excess of silica over lime. For the first trial, therefore, let this amount of limestone be raised to 170 lb. Enter this together with its calculated constituents in line *c*.

The coke for the charge as thus determined will be $(1000 + 115 + 170) \text{ lb.} \times 0.14 = 1285 \text{ lb.} \times 0.14 = 180 \text{ lb.}$ Enter this amount of coke in line *d*, calculating its constituents.

The totals of silica, iron, lime, and sulphur are now entered in line *e*, and the charge is tested as follows. From amounts in lines,

Sulphur to matte and slag = 51.1 lb. $\times$ 0.80 =	40.9 lb.
Sulphur to slag = 254 lb. $\div$ 34 =	7.5 lb.
Sulphur to matte =	33.4 lb.
Iron on charge for matte and slag =	227 lb.
Iron to matte = 33.4 lb. $\times$ 2 =	67 lb.
Iron for slag =	160 lb.
Iron required by silica = 254 lb. $\times$ 0.640 =	163 lb.
Deficit of iron =	3 lb.
Lime on charge for slag =	210 lb.
Lime required by silica = 254 lb. $\times$ 0.824 =	209 lb.
Excess of lime =	1 lb.

The charge as it stands shows a deficit of iron amounting to 3 lb. and an excess of lime amounting to 1 lb. While this would not be a serious matter in practice, for the present purpose it will be better to correct the condition. The desired change may be effected by cutting the amount of silicious ore on the charge. It will be recalled that this material contains about 42 per cent of silica in excess of iron. The removal of 10 lb. of it from the charge will therefore decrease the amount of free silica by about 4 lb., and this according to the slag ratio will correct the deficit of iron. At the same time a decrease in the silica will destroy the balance of the charge with respect to lime. Consequently, a cut in the limestone will also have to be made. Reasoning in a manner similar to the above shows that this cut should also be about 10 lb.

For the second trial enter 1000 lb. of D. and L. sinter in line *f*, 105 lb. of silicious ore in line *g*, 160 lb. of limestone in line *h*, and 177 lb. of coke in line *i*. The components are to be calculated as usual, totals being entered in line *j*.

Considering these totals,

Sulphur to matte and slag = 50.5 lb. $\times$ 0.80 =	40.4 lb.
Sulphur to slag = 249 lb. $\div$ 34 =	7.3 lb.
Sulphur to matte =	33.1 lb.
Iron for matte and slag =	226 lb.
Iron to matte = 33.1 lb. $\times$ 2 =	66 lb.
Iron for slag =	160 lb.
Iron required by silica = 248 lb. $\times$ 0.640 =	159 lb.
Excess of iron =	1 lb.
Lime on charge for slag =	204 lb.
Lime required by silica = 248 lb. $\times$ 0.824 =	204 lb.

This works out a little better than the previous trial, though both of them are good, and either would be sufficiently correct.

The amount of lead on Charge A as it was last calculated is

Lead from 1,000 lb. D. and L. sinter = 1,000 lb. $\times$ 0.2950 =	395.0 lb.
Lead from 105 lb. silicious ore = 105 lb. $\times$ 0.123 =	12.9 lb.
Total =	408 lb.

$$\text{Per cent of lead on Charge A} = \frac{408 \times 100}{1265} = 32.5.$$

Passing now to the calculation of Charge B, the first step consists of entering 1000 lb. of the silicious ore on the charge sheet. It is seen in line *k* with the amounts of its constituents properly entered.

The amount of silica present in this material in excess of iron has already been estimated at 42.3 per cent. Hence, in the 1000 lb. there will be 423 lb. of silica to be provided with iron. Considering the iron ore analysis, the 12.6 per cent of silica will require $12.6 \times 0.640 = 8.1$ per cent of iron. The 1.94 per cent of sulphur present will require about 2 per cent of iron for matte. There remains $55.3 - 10.1 = 45.2$ per cent approximately of iron in excess of the silica and sulphur. The iron ore required for 423 lb. of silica in the silicious ore will therefore be

$$\frac{423 \text{ lb.} \times 0.640}{0.452} = 599 \text{ lb.}$$

As in most of the previous cases, however, this amount of iron ore will not be sufficient for the entire charge, because the limestone and coke are both yet to be added, and both contain an excess of silica over iron. As a first trial let the amount of iron ore be increased beyond this estimate to 650 lb. Enter this amount with its constituents in line *l*.

Now, consider the amounts of silica and lime in lines *k* and *l*.

Lime required by 583 lb. silica = 583 lb. $\times$ 0.824 =	480 lb.
Lime present =	34 lb.
Lime to be supplied =	446 lb.

It has already been seen that the limestone contains 40.6 per cent of lime in excess of silica. Hence the limestone required to provide 446 lb. of lime is

$$\frac{446 \text{ lb.}}{0.406} = 1100 \text{ lb.}$$

What is to be done with this? Shall 1100 lb. of limestone be entered on the charge sheet? No, because the coke contains silica in excess of lime, and this amount of limestone would prove insufficient for the entire charge. Let it be increased to 1125 lb. Enter this in line *m* with its calculated constituents.

Coke for this charge will be: $(1000 + 650 + 1125) \text{ lb.} \times 0.14 = 2775 \text{ lb.} \times 0.14 = 388 \text{ lb.}$ Enter this amount and constituents in line *n*.

Considering the totals of line *o*,

Sulphur to matte and slag = 71.5 lb. $\times$ 0.80 =	57.3 lb.
Sulphur to slag = 685 lb. $\div$ 34 =	20.2 lb.
Sulphur to matte =	37.1 lb.
Iron on charge for matte and slag =	518 lb.
Iron to matte = 37.1 lb. $\times$ 2 =	74 lb.
Iron to slag =	144 lb.
Iron required by silica = 686 lb. $\times$ 0.640 =	439 lb.
Excess of iron on charge =	5 lb.
Lime on charge for slag =	564 lb.
Lime required by silica = 686 lb. $\times$ 0.824 =	565 lb.
Deficit of lime =	1 lb.

The excess of iron amounting to 5 lb. may be adjusted by cutting 10 lb. from the iron ore. The limestone may be left as it is, because this cut in the iron ore will naturally adjust the 1 lb. deficit of lime by removing silica from the charge.

Amounts for the second trial will therefore be silicious ore 1000 lb., iron ore 640 lb., limestone 1125 lb., and coke (14 per cent) 387 lb. Enter these in lines *p*, *q*, *r*, and *s*, with totals in line *t*.

Considering the totals in the last line,

Sulphur to matte and slag = 71.5 lb. $\times$ 0.80 =	57.0 lb.
Sulphur to slag = 685 lb. $\div$ 34 =	20.1 lb.
Sulphur to matte =	36.9 lb.
Iron on charge for matte and slag =	513 lb.
Iron to matte = 36.9 lb. $\times$ 2 =	74 lb.
Iron to slag =	439 lb.
Iron required by silica = 685 lb. $\times$ 0.640 =	438 lb.
Excess of iron =	1 lb.
Lime on charge for slag =	564 lb.
Lime required by silica = 685 lb. $\times$ 0.824 =	564 lb.

The charge is satisfactorily balanced.

The amount of lead on Charge B as last calculated is lead from 1000 lb. silicious ore = $1000 \text{ lb.} \times 0.1230 = 123 \text{ lb.}$

$$\text{Per cent of lead on charge} = \frac{123 \times 100}{2765} = 4.45$$

Requirement *a* in the statement of the problem asks for the amounts of silicious ore, iron ore, limestone, and coke to be smelted with 1000 lb. of the D. and L. sinter in order to have present 12.0 per cent of lead on the charge. The per cent of lead on Charge A is 32.5, and that on Charge B is 4.45. In what proportions will A and B have to be mixed to have 12.0 per cent of lead present in the mixture?

Let *a* = the per cent of Charge A in such a mixture and *b* = the per cent of Charge B in the mixture.

Then

$$a + b = 100$$

and

$$0.325a + 0.0445b = 12.0.$$

Solving, *a* = 26.8 per cent, and *b* = 73.2 per cent.

The weight of Charge A as calculated is 1265 lb. This contains 1000 lb. of the D. and L. sinter. Hence the final charge will weigh

$$\frac{1265 \text{ lb.}}{0.268} = 4720 \text{ lb.,}$$

it being necessary to have 26.8 per cent of Charge A in order that the lead may be 12.0 per cent of the charge. Of Charge B there will be required for the final charge 4720 lb. — 1265 lb. = 3455 lb. Since Charge B as calculated weighed 2765 lb., the amount of each material therein to be employed in the final charge may be found by multiplying the original figures by

$$\frac{3455}{2765} \quad 1.25$$

Thus

Silicious ore, 1,000 lb. $\times$ 1.25 =	1,250 lb.
Iron ore, 640 lb. $\times$ 1.25 =	800 lb.
Limestone, 1,125 lb. $\times$ 1.25 =	1,405 lb.

The final combination of Charges A and B will therefore be as follows:

D. and L. sinter =	1,000 lb.
Silicious ore, 1,250 lb. =	1,355 lb.
Iron ore =	800 lb.
Limestone, 1,405 lb. =	1,565 lb.
Total =	4,720 lb.
Coke = 14 per cent of charge =	660 lb.

Requirement *b* in the statement of the problem asks for a calculation of the lead distribution among the various products formed during the smelting operation. These conditions are assumed, that the amount of matte produced is found to agree with the calculated matte fall, that the matte contains 12.5 per cent of lead, that the amount of bullion produced is 10.3 per cent of the charge and contains 97.0 per cent lead, and that the slag produced contains 0.68 per cent lead.

In order to solve this part of the problem it is neces-

sary to employ the final charge as outlined above. The information needed may be conveniently assembled in the following form:

Material	Weight, lb.	Lead, lb.	Silica, lb.	Sulphur, lb.
D. and L. sinter.....	1,000	395	175	42.5
Siliceous ore.....	1,355	167	679	72.9
Iron ore.....	800	...	101	15.5
Limestone.....	1,565	...	117	...
Coke.....	660	...	34	8.1
		562	1,106	139.6

The above total figures yield the following:

Sulphur to matte and slag = $139.6 \text{ lb.} \times 0.80 =$	111.5 lb.
Sulphur to slag = $1106 \text{ lb.} \div 34 =$	32.5 lb.
Sulphur to matte =	79.0 lb.

If this sulphur constitutes 23.0 per cent of the matte, then the amount of matte produced from the charge is

$$\frac{79.0 \text{ lb.}}{0.230} = 343 \text{ lb.}$$

Lead contained in the matte = $343 \text{ lb.} \times 0.125 =$	42.9 lb.
Lead in slag = $1,106 \text{ lb.} \times \frac{34}{0.68}$ (ratio lead to silica) =	22.1 lb.
Lead in bullion = $4,720 \text{ lb.} \times 0.103 \times 0.970 =$	472 lb.
Lead accounted for =	537 lb.
Lead loss to stack = $562 \text{ lb.} - 537 \text{ lb.} =$	25 lb.

The distribution of the lead is therefore

Product	Lead, lb.	Per Cent
Bullion.....	472	84.1
Matte.....	42.9	8.5
Slag.....	22.1	3.9
Dust, fume, etc.....	25	4.5

CONCLUSION

The practising lead metallurgist, if he ever takes the time to look through these problems, will no doubt find much in them that is open to criticism. To all sins of omission or commission that may be thus disclosed the writer pleads guilty in advance. It is not with the intention of instructing the metallurgist in his business that these problems have been presented, but rather to fix in the mind of the student a few facts concerning charge calculations and the metallurgy of lead, which, without actual practice with numerical examples, he frequently fails to grasp.

The Recovery of Benzol from Gas*

By F. W. Sperr, Jr.

Chief Chemist, H. Koppers Co.

One of the most noteworthy achievements in American chemical industry during these last two eventful years has been the rapid development of the recovery of benzol from coal gas. Associated principally with the manufacture of by-product coke, the business of recovering benzol in this country had previously lagged behind the parent industry which was already beginning to make striking progress three or four years before the outbreak of the great war. The lag was due, partly, to a seeming lack of real demand for the material; partly to the abundance of petroleum, and partly, also, to the groundless fear that the operations necessary for the recovery of benzol would add too many complications to the manufacture of by-product coke.

Thus, at the close of 1913 there were about sixteen plants in the United States making light oil from coke-oven gas. Most of the product from these plants was used for the enrichment of illuminating gas, leaving a comparatively small amount of material for other purposes. There were only two or three small plants for the manufacture of pure benzene, toluene, etc.

Even at that time, however, there were signs that the importance of the recovery of benzol was gaining

recognition, and it is likely that the advancing price of gasoline would soon have led to a large extension of the industry even without the stimulus of war prices.

From the close of 1914 to the summer of 1915 the prices of benzol products rose with the cessation of foreign supply and the ever increasing necessities of the munition business, until pure benzene commanded over 80 cents per gallon and toluene was sold as high as \$7.00 per gallon. The response was rapid. The first complete modern plant for the large-scale production of pure benzene and toluene was put into operation in May, 1915, and the total production of benzol products in the United States in that year rose to over twenty-two million gallons—more than twice as much as had been produced the previous year.

At present writing (January 1, 1917) there are about forty benzol recovery plants in operation in connection with by-product coke plants, having a capacity of approximately thirty million tons of coal per annum. Making due allowance for the facts that a number of these plants scrub only part of their gas and that part of the benzol is immediately used for enrichment, a conservative estimate would place the present annual light oil production at not less than forty million gallons. Three of these plants are now being enlarged, and eight new plants are in course of construction. The completion of this new work will bring the annual production of light oil up to nearly fifty million gallons.

The prices of benzene and toluene, although lower than the abnormal figures of two years ago, are still firm, the former at about 55 cents per gallon and the latter at about \$1.75 to \$2.50 per gallon.

It is to be especially noted that the increase of output has been almost altogether in the production of pure products; the amount of unrefined benzol now being made is probably actually less than was made in 1914. It appears probable that at least 80% of the present production is redistilled for the preparation of pure benzene and toluene.

USES OF BENZOL

The question is frequently asked: "What will become of this vast production of benzol after the war?" It must be remembered, in the first place, that the use of the benzol group of explosives, particularly trinitrotoluol and tetranitroaniline, is by no means confined to military purposes, and their consumption for commercial blasting operations will doubtless increase to a very large extent, because the war has given such a convincing demonstration of their superior qualities. The demand for military explosives is likely to continue on a considerably greater scale than before the war on account of the increased amount of military training that is being required in every country, and on account of the general recognition of the wisdom of accumulating and storing large reserve supplies of the principal explosives. It is one of the peculiar merits of trinitrotoluol that it can be stored indefinitely without risk of deterioration, and the importance of conserving this valuable asset in national defense cannot be overestimated.

The vast development of American chemical industries insures a market for large quantities of benzol products to be used for synthetic purposes. Benzene, itself, is an indispensable source of nitrobenzene and aniline with its long series of valuable derivatives. The manufacture of synthetic phenol, which is far outstripping that of carboic acid made directly from coal tar, may be considered as a very important outlet for pure benzene on account of the great increase in the production of the various condensation products of phenol and formaldehyde. From toluene we obtain such well

*A paper read before the American Institute of Chemical Engineers, New York City, Jan. 12, 1917.

known products as benzaldehyde, saccharin and benzoic acid. Metaxylene is the source of a rather important series of dyes. The study of the other materials contained in smaller amounts in coke oven benzol and available for the production of many interesting series of synthetic chemicals has barely begun, but promises to afford striking results in the not far distant future.

Passing thus briefly over the consumption of benzol in the chemical industries, let us consider its employment as motor fuel. So far as bulk is concerned this bids fair to surpass any other possible source of demand. Previous to the war, Germany used over 50% of its benzol production for the operation of internal combustion engines. J. S. Critchley, president of the British Institution of Automobile Engineers, is quoted as stating that the carburetion of benzol presents no difficulties and that in actual practice the material gives an increase of mileage of about 20% over gasoline, affording at the same time 12 to 15 per cent more power. A series of tests made in 1913 at Brooklands, England (*Gas World*, Sept. 6, 1913, Coking and By-Product Section, page 9), showed an average of five miles increase per gallon.

The demands of the automobile industry alone are so great as to preclude the possibility of any destructive competition between benzol and gasoline. As was stated early in this paper the benzol recovery plants now in course of construction, together with those already operating, will make an annual production of about fifty million gallons of benzol. There are now over two million automobiles in operation in this country so that the contemplated benzol production would give each machine about 25 gallons. If all the coke that the country now requires were coked in by-product ovens with benzol recovery apparatus we should expect a total annual benzol production of about 110 million gallons or 55 gallons per machine. This total benzol production would be less than half the amount of gasoline and naphtha exported in 1915.

Other uses of benzol may be rapidly summarized for sake of completeness. Quantities are employed in the manufacture of paints, stains, varnishes and lacquers; in the cleaning industry; in the extraction of grease and fats; as solvents for rubber and for the manufacture of artificial leather and insulating materials. Lastly may be mentioned one use which should be considered rather as an economic waste than of benefit to the industry. This is for enriching illuminating gas to make it conform with antiquated candle power standards based on the use of flat flame burners. The utilization of mantle burners and the increasing tendency to replace old candle power specification by calorific standards, already universally adopted in more advanced European practice, will doubtless soon do away with the necessity for gas enrichment, and make it possible for large illuminating gas plants to recover their benzol and utilize it for more rational purposes.

PRINCIPAL OF BENZOL RECOVERY PROCESS

Before proceeding with the technical description of the benzol recovery process it may be well to give a few moments' consideration to the gas from which the material is extracted. The gases produced by the high-temperature distillation of coal are extremely complex in composition, but we may consider their constituents as grouped in two classes, viz., easily condensable and difficultly condensable substances, the former solid liquid or very soluble in water at ordinary temperatures, the latter gaseous and difficult to liquefy. Most of the substances of the first group such as water, ammonia, and the heavy hydrocarbons of tar, are removed by the usual operations of condensation and treatment with fresh water or acid. The amount and nature of the

easily condensable substances left in the gas after undergoing these operations depends upon the vapor tension of each. Substances of a relatively high vapor tension such as benzene and toluene remain, to a large extent, uncondensed. Only 5% of the total benzol in the gas is removed with the tar in the condensing plant. Actually, of course, the gas after leaving the plant, contains slight amounts in the form of vapor, of all the original condensable substances, but the quantities of substances having higher boiling points than that of naphthalene (218° C.) are practically negligible.

Exclusive of water, the easily condensable vapors remaining in ordinary coke oven gas after the usual process of condensation and ammonia recovery, amount to about 1% by volume of the gas. They might be removed by cooling the gas to a very low temperature and this was actually done on a large scale in Europe some years ago, but the method was handicapped by mechanical difficulties largely due to the separation of ice and has been altogether abandoned. The only practical alternative which can be employed to recover these vapors, without altering their chemical constitution, is to treat the gas with a medium in which the vapors are soluble and from which they may be recovered by simple distillation.

This is the principle of every benzol recovery process in operation at the present time. It appears to have been first employed in 1859 by Vogel, who washed coal gas with fatty oils for recovering the benzol. It is peculiar that Vogel had only the idea of enriching these oils so as to improve their quality for illuminating purposes. Various processes for extracting benzol based on this principle were later patented; but it was not until 1887 that it was put into successful commercial operation. This was done in Germany by F. Brunk, who is generally acknowledged as being the founder of the modern benzol recovery industry.

It is a peculiar circumstance that the condensable hydrocarbon vapors belong almost entirely to the aromatic series. Benzene together with its homologues, toluene and the xylenes constitutes over 85%. Other substances present in much smaller amounts are carbon disulphide, thiophene, pyridine, naphthalene, and various olefines of both cyclic and open chain structure. Members of the paraffin series of hydrocarbons are almost entirely absent. The mode of formation of these compounds in the destructive distillation of coal, the effect of various conditions of carbonization, such as temperature and rate of heating on the character and amounts of the various substances formed, and the variation in the quality and quantity of the products from different groups of coals, are subjects of extreme interest on which our conceptions are not yet by any means clearly defined. The most important generalization that we are able to make is that the maximum yields of benzene and toluene are obtained at moderate coking temperatures. Higher temperatures have a tendency to form more benzene apparently at the expense of the toluene and extremely high temperatures decrease the yields of both benzene and toluene.

The percentages of the more important constituents of typical coke oven light oil and the amounts usually produced per ton of coal 2000 lbs. are given herewith:

TABLE I—AVERAGE COMPOSITION OF COKE OVEN LIGHT OIL	
	Per Cent in Light Oil Gallons per Ton Coal
Benzene	66 1.782
Toluene	15 0.405
Xylene	8 0.216
Other substances	11 0.297
(principally hydrocarbons)	
Total	100 2.700

For sake of convenience a table of the more important properties of some of the constituents of light oil is also inserted. In the preparation of this table the literature has been exhaustively investigated and every endeavor has been taken to present the data as accurately as possible.

OPERATION OF A BENZOL RECOVERY PLANT

In discussing the operation of a benzol recovery plant of modern type I shall deal principally with the Koppers patented process, because I have made a rather special study of this process as being typical of modern practice. To the best of my knowledge all of the coke oven benzol plants now under construction in America, with possibly one or two exceptions, are of this type.

In America the wash oil generally used to absorb the benzol is a petroleum product usually known as straw oil, of which at least 90% should distil between 250 and 350° C. A good absorbent oil has a specific gravity of less than 0.88 at 15° C. and is readily fluid at 4° C. It contains no naphthalene or pitch and exerts a good solvent action on benzol. In best practice the amount of benzol absorbed (technically the "enrichment") is kept between 2 and 3% of the absorbing oil. Too high enrichment is likely to lead to loss of benzol and too low enrichment may involve needless consumption of absorbing oil. In European practice heavy tar oils used almost exclusively as absorbing and steam media and such materials may find increasing application in America. Such tar oils should contain less than 7% naphthalene and 90% of the material should distil between 200 and 300° C.

Fig. I shows a flow sheet of a benzol plant showing the principal features of operation. Let us follow first

the course of the gas and then that of the oil. Previous to treatment with the absorbing oil, the gas should be cooled to a suitable temperature which may vary from plant to plant and depends principally upon such factors as its moisture and naphthalene content, temperature of the wash oil, and percent enrichment desired. This cooling is accomplished by means of the cooler (A), which is preferably of the direct contact type. The water not only acts as a cooling medium, but mechanically washes a large portion of the naphthalene out of the gas and carries it into the separating sump (B). The cool gas then passes into the benzol washers (C). These are tall scrubbing towers of the hurdle type, effecting a very intimate and prolonged contact between gas and oil. The debenzolized gas passes out of the last washer through the return main to its point of consumption.

The fresh wash oil is pumped from the circulating tank (D) over the scrubbers in an opposite direction to the flow of the gas, maintaining the counter-current principle that should be adopted in nearly all scrubbing operations and bringing the fresh washing medium into the scrubbing system at a point where the gas contains the least light oil vapors. The distribution of the wash oil over the tops of the scrubbers is a very important matter, and should be done as uniformly as possible. The enriched wash oil accumulates in tanks usually located underneath the scrubbers, and is pumped from these to the benzol recovery plant to be heated for the purpose of releasing its benzol constituents.

Part of this heating is accomplished in the Koppers System by the utilization of the heat in the hot debenzolized wash oil leaving the still. Two heat economizers are used in this system. The cold oil first enters the heat exchanger (E), where it is heated by benzol vapors and steam from the still (H), thence it is conducted to a second heat exchanger (F), where it receives additional heating by means of hot debenzolized wash oil leaving the still (H). It is then still further heated to the maximum temperature desired by means of live steam in a superheater (G), from which it passes into still (H), this still is composed of a series of superimposed sections or chambers as in common distillation practice. The heated oil flows down through these sections while steam is blown directly into the lowest section and travels in a direction opposite to that of the oil. The mixture of benzol and water vapor is partially rectified in the upper portion of the still, and then enters the heat exchanger (E) as mentioned be-

ferent boiling points preliminary to washing and final rectification. This and subsequent distillations are made intermittently in stills of large capacity (6000 to 12,000 gal.), which give better fractionations than are possible in smaller apparatus. The continuous type of stills has not been found satisfactory in this work. The crude still does not require the elaborate dephlegmator, that is necessary on the final rectifying stills. The heating is accomplished by means of internal steam coils and a direct steam spray. The benzol and toluol are principally distilled off by indirect heat, using the steam coils, and the higher boiling constituents xylol, solvent naphtha, etc., are then distilled over by introducing steam directly into the still.

After the benzol, toluol, xylol and solvent naphtha have been distilled off, a certain amount of wash oil containing naphthalene remains in the still tank. The presence of wash oil in the light oil is due not only to mechanical trapping of the heavy oil during the distillation, but also to the actual distillation of some of its original constituents by agency of the direct steam used. The products recovered from 1000 gal. of light oil vary according to the kind of coal coked, the regulation of the ovens and the method of operation of the light oil plant. In one plant that may be taken as fairly typical of a well-operated system the yields average about as follows:

From 1000 gal. crude light oil.
680 gal. crude benzol.
140 gal. crude toluol.
50 gal. crude xylol.
55 gal. solvent-naphtha.
75 gal. wash oil residue with naphthalene.

The wash oil remaining in the still is drained into cooling pan (M), where it is cooled in the air to crystallize out the naphthalene. The wash oil is drained away from the latter into tank (N), and then is returned to the main circulating tank (D). In large plants where the amount of naphthalene is great, a centrifugal dryer is employed for the purpose of separating the small amount of oil remaining in the naphthalene, and also for reclaiming the naphthalene from the separating

sump at the foot of the gas cooler. The crude naphthalene so obtained can be sold as such, or may be put into the tar in the coke plant.

The products obtained from the crude still will satisfy many commercial purposes in normal times. Moreover, at present the demands of chemical manufacturers for benzol and toluol of a high degree of purity have made it advisable to accomplish the complete process of purification at the coke plant to serve this important part of the trade. For this purification the crude benzols are first washed with sulphuric acid and then with caustic soda and water. This operation is accomplished in agitator (O), which is a large lead-lined vessel with an efficient mechanical mixing device for bringing the acid and benzol into intimate contact. The acid is commercial concentrated sulphuric acid (66 deg. Bé). The quantity used is accurately measured from the meter tank (p). The caustic soda solution is prepared in the tank (Q) and measured in the meter tank (p₁).

The acid has the effect of reacting with and to a large extent polymerizing most of the impurities which consist of various olefines and substances of similar character, together with certain phenoloid bodies. This results in the formation of resinous substances of very high boiling point, part of which are insoluble in the benzols and settle out with the acid in the bottom of the agitator, while part go into solution, giving the benzol a dark brown or a reddish color. The acid sludge is drawn off and treated, as will be described later. The caustic soda neutralizes any traces of acid which may remain in the agitator and effect the removal of some of the phenoloid bodies. After the soda wash the benzol is a lighter brown color, but always requires distillation. The washed benzol is delivered from the agitator to the still (R). This still is generally of the same capacity as the crude still, but is provided with a very efficient dephlegmator. Sometimes purified products of less exact boiling points are desired. In this case the washed benzols are distilled rapidly, simply to separate the benzol from the resinous materials in solution. The products so produced are termed "purified," e.g. 90 per cent purified benzol, 50 per cent pure benzol,

FIG. 3—BENZOL RECOVERY PLANT—WASH OIL STILL AND CRUDE STILL

FIG. 4—BENZOL RECOVERY PLANT—CRUDE AND PURE STILL

etc., the nomenclature being based on the percentage in test distilling under 100 deg. C. The distillation for the preparation of pure products is conducted more slowly, the condensate being collected in receivers (S), and tested carefully before placing in the final storage tanks.

Great improvement has been made in recent practice in the distillation of pure benzol and toluol. In a well-designed plant the cuts are remarkably clean and the percentage of intermediate fractions small. At one benzol plant pure benzene is regularly being produced of a grade such that less than 5 per cent. distils below 80.1 deg. C. and 95 per cent distils within 0.3 deg. C. Pure toluene also is being made of which less than 5 per cent distils below 110.0 deg. C. and 95 per cent within 0.5 deg. C. This extraordinary degree of purity is of great advantage to manufacturers of explosives and synthetic chemicals requiring the use of pure benzols. The ease with which these distillations can be effected and the sharpness of the cuts obtained is very remarkable. Much of the secret of success lies in the correct design of the dephlegmator. The record of one plant shows the following average figures for the distillation of crude benzol containing toluene:

Pure benzene	85.3%
Intermediates	3.4%
Pure toluene	9.8%
Residue	1.3%
Loss	0.2%

The residue is often allowed to go to waste; but may be mixed with the coke-oven tar without injury.

The water and caustic soda used in the agitator are drained to the sewer. The acid sludge drained from the agitator is delivered to a boiler (T), in which it is treated with direct steam. This effects a separation of the resinous materials in the form of a heavy carbonaceous spongy deposit. An acid of about 40 deg. Bé is recovered and may be used on the coke plant for making ammonium sulphate. The boiler is covered during the operation of steaming and the escaping vapors are condensed in a cooler.

Regarding other details, such as the arrangement of pumps, storage tanks and piping, the diagram is self-explanatory.

The upkeep of a benzol plant costs remarkably little and the labor required in operation is small. A complete plant handling 5000 gal. of light oil per 24 hr. is operated by five men on day turn and three men on night turn, with two chemists for control testing and three laborers on day turn only for loading shipments and for general utility purposes.

The apparatus that is subjected to the most severe conditions is the superheaters. Spare superheaters should always be provided and the apparatus arranged so as to be readily interchanged. All apparatus for heating and cooling the wash oil should be so arranged that each individual unit can be taken out easily without disturbing the other apparatus. All apparatus with the exception of that exposed to sulphuric acid is made of iron and steel, no special alloys being required. It is very essential that the utmost precaution be taken in the arrangement of the piping to obviate the possibility of accidental mixing of the different products.

Since benzol is a by-product of coke and gas making, those items in the cost of its production which are involved also in coke and gas production, are not chargeable to the benzol. In other words, the cost of making coke-oven benzol includes only the cost of its extraction from the coke-oven gas, and that of its purification. This cost in the United States will vary according to local conditions, but usually lies between 4.0 and 7.0 cents per gallon.

At the close of the European war, when prices again become normal, it will be possible with the large plant capacity then available to make a substantial profit from the production and sale of automobile benzol (90 per cent-purified) at prices competing with those of gasoline. There are other large uses creating a demand for the various benzols, described in earlier paragraphs and further uses will be developed as the supply of the material becomes greater.

The effect of the removal of benzol on the calorific value of the gas has been well worked out by J. W. Shaeffer, who recently published his results in an article read before the October, 1916, meeting of the American Gas Institute. The actual loss in the calorific value of the gas amounts to about 5.8 per cent, which is a figure representing the average practice of about thirty by-product coke plants. The figure agrees well with theoretical considerations. The result is that more debenzolized gas has to be used for accomplishing a given heating effect. Assuming that one ton of coal makes 11,000 cu. ft. of gas, a reduction of 5.8 per cent is equivalent to 638 cu. ft. less gas. As boiler fuel this gas is worth about 6 cents per 1000 cu. ft., so that the reduction may be figured to cost about 3.83 cents per ton of coal, i.e. about 8 per cent of the normal value (based on gasoline prices) of the total benzol recovered.

H. Koppers Company Laboratory, Mellon Institute,
Pittsburgh, Pa.

Chemical and Electrical Porcelain

Joint Meeting of American Electrochemical Society,
American Chemical Society, and Society of
Chemical Industry

Authorities on the subject of ceramics will talk on the manufacture of "chemical and electrical porcelain" in the United States at a joint meeting of the American Electrochemical Society, American Chemical Society and Society of Chemical Industry to be held at the Chemists' Club, on Friday evening, February 9. The speakers will be L. E. Barringer, of the General Electric Company, president of the American Ceramic Society; A. V. Bleining, of the Bureau of Standards, Pittsburgh; and Charles F. Binns, director of the New York State School of Clay Working and Ceramics, Alfred, N. Y.

The development of the manufacture of porcelain in the United States since the war has been very rapid. Before the war all of the better grades of porcelain and ceramics were imported, but this country is now making products which compare very favorably with those products formerly imported. In the manufacture of electrical porcelain this country excels all other countries. Samples of some recent products will be shown.

Detroit and Pittsburgh Meetings of American Electrochemical Society

The spring meeting of the American Electrochemical Society will be held at Detroit, Mich., from Wednesday, May 2, to Saturday, May 5, inclusive. On May 2, visits to automobile plants will be made, with a "get-together" roadhouse dinner in the evening. On May 3, sessions will be held for Electric Steel, Ferroalloys, and general papers, with a smoker in the evening. On May 4, there will be sessions on Non-Ferrous Metals, and Low-Temperature Electrochemical Processes, followed by visits to electric steel plants and power houses in the afternoon, and addresses by President Fitzgerald and Mr. Alexander Dow in the evening. The session of May 5 will be devoted to electrodeposition of metals, theory and prevention of rusting of iron.

The fall meeting will be held in Pittsburgh, from Wednesday, October 3, to Saturday, October 6, inclusive.

Presentation of the Perkin Medal to Ernst Twitchell

On Friday evening, Jan. 19, in Rumford Hall, Chemists' Club, before a splendid gathering and amid suitable patriotic decorations, the Perkin Medal for this year was formally presented to Dr. Ernst Twitchell for his work on the hydrolysis of fats, in a meeting of the New York Section of the Society of Chemical Industry, held jointly with the Sections of the American Chemical Society and the American Electrochemical Society.

Dr. JEROME ALEXANDER, chairman of the New York Section of the Society of Chemical Industry, presided. He first made the announcement that Dr. Parker C. McIlhiney, secretary of the New York Section for many years, had resigned and that Dr. Allen H. Rogers had been appointed to fill his place. A rising vote of thanks was tendered to Dr. McIlhiney for his long and efficient service as secretary of the New York Section.

In coming to the subject of the evening, Dr. Alexander gave a brief review of past Perkin medal awards and of notable discoveries in general in America. He said America has contributed more than her share of the notable discoveries of the world and not a few of these have been in the field of chemistry. In introducing DR. CHAS. F. CHANDLER, the presentation speaker, as the "dean of the chemical profession in America," he took occasion to congratulate him on the celebration of his eightieth birthday.

Dr. Chandler then delivered his presentation address, which is printed in full below, reviewing briefly the state of the art prior to Dr. Twitchell's work and giving a résumé of his work. He then presented to Dr. Twitchell the medal, with a few felicitous remarks "as a token of the esteem and affection of his fellow chemists."

Dr. TWITCHELL accepted the medal with a few words of thanks for the appreciation of his work, and followed with a history of his discoveries in the hydrolysis of fats. He was followed by Dr. A. C. LANGMUIR of Marx & Rawolle, Brooklyn, N. Y., who told about the Twitchell process in the glycerin trade, by Dr. MARTIN H. ITTNER of Colgate & Co., Jersey City, N. J., who spoke on the Twitchell process in the soap and candle industry, and by Mr. HERMAN B. SCHMIDT, who concluded the program with some interesting personal reminiscences.

The evening was very enjoyable. The speeches were brief and to the point. Their full text follows:

Presentation Address

By C. F. Chandler

It is my privilege and very pleasant duty as Senior Past President of the Society of Chemical Industry, residing in this country, to present to Ernst Twitchell, B.S. and D.Sc., the eleventh impression of the Perkin Medal, in recognition of his most original and valuable work in Applied Chemistry.

Dr. Twitchell was born in Cincinnati, on February 26, 1863. He graduated in 1886 from the University of Cincinnati with the degree of B.S., and in 1915 received from his alma mater the honorary degree of Doctor of Science. On his graduation in 1886, he was appointed chemist to the Emery Candle Company of Cincinnati,

and has been connected with that firm ever since. At present he is chemical director to the Emery Candle Company, president of the American Oil Treating & Hardening Company, and chairman of the Board of Directors of the Twitchell Process Company.

Dr. Twitchell has devoted the past thirty years chiefly to the chemistry of fats. His investigations and discoveries have been given to the chemical world in the form of articles in various chemical journals and in letters patent of the United States and other countries.

In 1891 he published his method for the determination of rosin in the fatty acids of soap. The method is based on the fact, observed by him, that the fatty acids when dissolved in absolute alcohol, are readily and completely converted into ethyl ethers, by the action of dry hydrochloric acid gas which, absorbing the water

set free, acts to induce the reaction. On the other hand the rosin acids under the same treatment remain unchanged, and may be determined volumetrically with standard soda solution, or gravimetrically. Lewkowitsch, in his comprehensive work on "Oils, Fats and Waxes," remarks: "Of all the methods for determining rosin acids in the presence of fatty acids, the Twitchell method gives the best results."

Dr. Twitchell's most important contribution to industrial chemistry involves new and improved methods for the hydrolysis of oils and fats for the production of the free fatty acids and glycerin. These methods have very largely superseded the old methods such as that of Chevreul & Gay Lussac (in 1825), who saponi-

fied in open kettles with alkali. This process was improved by Milly in 1881, who substituted milk of lime for alkali, and later by conducting the saponification in closed vessels, under pressure, reduced the amount of lime required from 14 per cent of the fat to as low as 2 per cent. Then came the process of Dubrunfant first applied practically in 1842 by Jones and Wilson, in which the fat was saponified by sulphuric acid, and the fatty acids subjected to distillation.

Wilson and Gwynne later applied the discoveries of Bertholet and Melsens in a process in which the fat was decomposed by superheated steam and subsequent distillation, which was practiced at the works of Prices Candle Company, Battersea. Finally in 1854, Tilghmann introduced his process in which the fat, emulsified in water, was forced through a coil at a temperature of 320 deg. C. Marix found that by adding a little calcium or magnesium carbonate to the water, the temperature and pressure could be very materially reduced to as low even as 3 to 5 atmospheres.

The art of saponifying the fats had reached this stage of development when Dr. Twitchell made an entirely new departure by the application of new reagents, which by acting as catalysts, even when used in such small proportions as 1 to 2 per cent, are able to completely saponify the fats. The operation may be conducted by simply boiling the fat with water and the proper quantity of the "saponifier." The agents first employed by Dr. Twitchell were the sulfo-acids of the fatty acids, such as sulfo-stearic acid, sulfo-oleic acid, etc. Later

ERNST TWITCHELL

Dr. Twitchell found that by introducing an aromatic radical into the sulfo-acid, a much more satisfactory catalyzer was obtained; a sulfo-fatty aromatic acid. Such aromatic radicals as are furnished by benzene, phenol, and naphthalene are employed; naphthalene stearosulfonic acid being a favorite catalyzer.

These acids when converted into salts of such metals as barium, calcium, magnesium, aluminium, etc., can be produced as stable dry powders, to be used with a suitable proportion of sulphuric acid, or hydrochloric acid to make them active.

The Twitchell process has made possible the large scale saponification of fats for the production of crude glycerin free from salt and of fatty acids for direct combination with soda as to make soap instead of using the more expensive caustic lye on the neutral fat.

Low-grade fats, such as garbage grease, cottonseed oil foots, etc., were formerly with difficulty used in the soap or candle industry. Such materials can now be readily worked up by the Twitchell process, the fatty acids being distilled to remove color before use. This releases a large quantity of the higher grade fats for use as food products.

The bulk of the soap used in Belgium, Holland, Germany and Scandinavia is said to be prepared from fatty acids direct, and 75 per cent of these acids are made by the Twitchell method. Millions of pounds of fat are saponified yearly in the United States by this process, and practically all of the larger soap factories have Twitchell plants.

All of the recent books in German and English on the soap and fat industries discuss the Twitchell process in full.

Address of Acceptance of Perkin Medal

By Ernst Twitchell

The first suggestion which lead to my discovery of a special catalyzer for hydrolysing fats came to me in studying the so-called "acidification process." This was one of the oldest methods used in candle factories for separating glycerol from fatty acids. It consisted in treating the fat at a fairly high temperature, over 100 deg. C., with a small amount of concentrated sulphuric acid, 4 per cent or considerably less could be used; the product was then boiled with an excess of water. The result is a layer of fatty acids floating on the acid water containing the glycerol.

This reaction could not be explained by the assumption that there is a combination of sulphuric acid with the fat or fatty acid and glycerol, which decomposes during the subsequent operation of boiling with water, because there was not enough sulphuric acid to combine with all of the fat. Various theories have been given to explain the acidification process, some quite absurd. For instance, in one text-book it is stated that fats consist of minute globules surrounded by membranes and that the function of the sulphuric acid is simply to char and destroy these membranes, leaving the fat in a condition to be hydrolysed by water at 160 deg. Another theory was frequently seen even in recent articles; it stated that compounds are formed which cause the fat to emulsify with water, and the idea evidently is that if a good enough emulsion is obtained, hydrolysis will take place even at 100 deg. I have seen this theory given to account for the action of my hydrolysing reagent. As a matter of fact, fats do not hydrolyse at 100 deg., practically speaking, with water alone, even though they may be perfectly emulsified. At higher temperatures than 100 deg., and under pressure, hydrolysis takes place, as is illustrated in the autoclave process of separating glycerine.

In the course of practical experiments with the acidifi-

cation process I found that I could reduce the amount of sulphuric acid used very considerably and yet obtain complete decomposition; but often the boiling with water had to be decidedly prolonged. It seemed clear that there was some catalytic agent which caused the reaction between the fat and the water in this process of boiling, and it would naturally occur to any one that this catalyzer was probably some sulphur compound produced by the action of sulphuric acid on fat. I found that compounds of this nature could be roughly separated from the fat which contained them by treating with petroleum ether in which they were insoluble. They could be further purified by solution in ether and extraction with water and were easily identified as sulphonic acids by their acidity, the formation of potassium sulphate on fusion with caustic potash, and other characteristics.

It occurred to me to prepare this catalyzer outside of the body of the fat, thus avoiding the action of the sulphuric acid in forming with the fat undesirable compounds, in charring, discoloring, and partially destroying it.

As these sulphonic acids were probably produced by the action of the sulphuric acid on the oleic acid constituent of the fat, I first studied the results of the action of sulphuric acid on pure oleic acid under various conditions of temperature, quantity, etc.

The action of sulphuric acid on oleic acid at low temperatures, as was known, produces a compound of sulphuric acid, stearo-sulphuric acid, an acid sulphuric ester. This was not the catalyst that I was seeking. It very probably has all the properties of a catalyst for the hydrolysis of fats except one; it is decomposed on boiling with water, and as the hydrolysis of a fat hardly takes place at all under any circumstances at a temperature lower than 100 deg., it is plain that this compound would not serve my purpose.

The compounds obtained on treating oleic acid with sulphuric acid at a temperature of 100 deg. or over are not sulphuric acid compounds, but are true sulphonic acids. The principal one seemed to be derived from two molecules of oleic acid and contained one sulphonic acid group and one carboxyl group.

I have never seen this sulphonic acid described, but believe that I had in my hands a fairly pure compound of the composition $C_{54}H_{98}(SO_3H)COO$. $C_{54}H_{98}COOH$. This was my first hydrolysing reagent or saponifier. But as it was difficult to prepare commercially in fair yield and of any degree of purity, I dropped further investigation along this line on the accidental discovery of the fatty aromatic sulphonic acids, described in the *Journal of the American Chemical Society* of January, 1900.

In this research the most important question was: "What properties must a substance have to act as a catalyzer to accelerate the hydrolysis of fats?" My views on this subject I have partially expressed in my paper, "A Reagent in the Chemistry of Fats," published in the *Journal of the American Chemical Society* of February, 1906, where I say that it must be a strong acid, one dissociated strongly in water giving a considerable concentration of hydrogen ions; and then it must be soluble in both fat and water and cause the one to dissolve in the other.

The only bodies that I can at present conceive to have the desired properties are sulphonic acids containing higher fatty radicals. They have the physical character of fats or oils, yet are soluble in water forming soapy solutions, and are strong acids.

As I have said, the discovery of the fatty aromatic sulphonic acids was made by accident. I had a mixture of oleic acid and benzene, which I treated with an excess of sulphuric acid and then poured the mass

into water. I was not surprised to find an oily layer floating on the acid water, and when I found this oil to be soluble in pure water, that also did not surprise me, as I supposed I had simply stearo-sulphuric acid; but when I found that, after boiling, it still remained soluble, I felt sure that I had a sulphonic acid, and the analysis of the product confirmed my conclusion. This is the compound which has been put to practical use in the separation of glycerol and fatty acids. Instead of benzene, naphthalene is used with oleic acid in the manufacture of the commercial article. This "saponifier," when added in the proportion of half a per cent or less to fat boiling with water in an open tank, will cause the separation of the glycerol.

Besides the compound containing two stearic radicals and a sulphonic group, the first which I found to have the catalytic property, and the fatty aromatic sulphonic acids, I have also prepared hydrolysing reagents by treating oleic acid at 200 deg. to 220 deg. C. with sulphur, or in the cold with sulphur chloride (S_2Cl_2), and when oxidizing with nitric acid, potassium permanganate, bromine, or other oxidizing agent. The resulting compound contained one sulphonic and one carboxyl group and its molecular weight and other properties showed it to be a sulphonic acid of the stearic radical.

Belonging to this class of substances is a compound, cetyl sulphonic acid, described by A. Reyhler two or three years ago. When I saw this description I was sure that it was also a catalyst of the same type as my reagent, although Reyhler does not mention this as one of its properties.

As this is a typical compound, it may be interesting to describe how it was prepared, partly following directions given in Reyhler's paper. Cetyl alcohol, prepared by saponifying spermaceti with caustic potash and extracting the soap with petroleum ether, was converted into the iodide by dropping iodine into a heated mixture of the alcohol and red phosphorus. This iodide, after purification, was converted into the sulphhydrate by treating with alcoholic KHS and the cetyl sulphhydrate converted into cetyl sulphonic acid by oxidizing with potassium permanganate, the excess of which was reduced with sodium sulphite. The cetyl sulphonates could be freed from most of the foreign matter by taking up with hot water from which sodium cetyl sulphonate crystallized on cooling. This was dried, extracted with petroleum ether, then dissolved in water and treated with hydrochloric acid. The salted out cetyl sulphonic acid was dissolved in ether and remained in a nearly pure state as a residue on evaporating the ether. It can be further purified by crystallizing its sodium salt from dilute alcohol and there can be no doubt of its composition. It is a simple sulphonic acid of a hydrocarbon of the paraffine series.

Reyhler explains some peculiar properties of this compound in this way: The sulphonic radical tends to make it very soluble in water, while the long hydrocarbon chain has just the reverse effect. The result is that it forms colloidal solutions. Fahrion, in reviewing Reyhler's article, calls the cetyl sulphonic acid, "Reyhler's hydrogen soap," and that term, *hydrogen soap*, is as good a definition as I can think of to cover the whole group of compounds which catalytically induce hydrolysis of fats on the principle of my discovery. An alkaline soap plus hydrogen ions would no doubt have the same effect if it were possible to have such a combination. Besides its use in hydrolysing fats, my catalytic agent has been applied to other less important ones. A catalyst which would accelerate the hydrolysis of an ester in the presence of an excess of water would also accelerate the esterification of a fatty acid and an alcohol on the removal of the water

formed. Fatty acids can be made to combine with glycerol and other alcohols of high boiling point by simply treating a mixture of the two with a small quantity of the reagent and evaporating the water formed at 100 deg. C.

The solubility of sulpho-fatty acids in both fat and water leads to a method of separating solid and liquid fatty acids of which I have made some application. If a small quantity of the sulphonic reagent is dissolved in melted mixed fatty acids and the mixture allowed to cool, the solid acids will crystallize out pure and the liquid acids will contain the sulpho-fatty acids, being thus rendered slightly soluble in water, and on treating with water can be washed out from the mixture, partly in solution but mainly as an emulsion.

Patents have recently been obtained by Grigor Petroff of Russia on a reagent obtained as a by-product in refining petroleum with fuming sulphuric acid. This is a sulphonic acid of hydrocarbon radicals, probably both of the paraffine series. It is a very efficient catalyst in the hydrolysis of fats, for which purpose it is now largely used.

The Twitchell Process and the Glycerine Trade

By A. C. Langmuir

Some years ago a manufacturer asked my assistance in developing a chemical process. He wanted a process which would "cost nothing to work, would take nothing out of the product and would put nothing in." This man had heard nothing of catalytic methods, but his conception of the ideal chemical process which he was requiring corresponded closely to the modern catalytic methods such as the platinum contact process for the manufacture of sulphuric acid, which costs nothing to operate, once the contact mass is prepared, and which brings about the combination of sulphur dioxide and oxygen without adding an impurity which must be subsequently taken out or removing something which would lower the yield.

The Twitchell catalytic process goes far toward meeting this idea in the saponification or breaking up of fats and oil into their constituents, glycerine and fatty acids. Twitchell's invention (Patent 601,603, July 17, 1897) was made at a time when catalysis was not the universal subject of attention it is to-day. The Badische process for the catalytic production of sulphuric acid had not been published, and catalysis was a new thing in chemical industry.

Twitchell's work has been characterized by a sound appreciation of the work of physical and organic chemists and his analytical and technical methods have been worked out, not empirically, but from theoretical premises. Thus the Twitchell method for the determination of rosin in mixtures with fatty acids, as in soap analysis, rests upon the principle of the esterification of the fatty acids when treated with hydrochloric acid gas in presence of absolute alcohol and his discovery that resin acids when so treated refused to combine with the alcohol and could subsequently be separated as pure rosin. Although published in 1891, this method stands to-day as the most accurate process for the determination of rosin in presence of fatty acids.

Again in 1897 we find him bringing out a method for the separation of saturated and unsaturated fatty acids based upon the solubility of fatty acids with double bonds, such as oleic acid, in concentrated sulphuric acid at ordinary temperatures with the formation of sulfo-fatty acids soluble in water. The saturated fatty acids such as stearic acid are unacted on. In 1914 Twitchell makes use of the principle of the equal depression of the freezing point for equal molecular proportions and determines the composition of mixtures of fatty acids

by the observation of the freezing point in the Beckmann apparatus. To test whether a given sample of fatty acid is identical with a fatty acid of known character he adopts the novel plan of adding a portion of the known acid and noting whether there is any change in the melting point of the mixture.

Possibly his investigation of the action of concentrated sulphuric acid on fatty acids led to his discovery of the catalytic action of these sulfo-fatty acids in bringing about the decomposition of fats by water, as little as 0.5 per cent splitting up the fats almost completely on digestion with water.

The prevailing method for the manufacture of soap consists in the saponification of the fat by boiling with caustic soda lye. The fatty acids combine with the soda as soap, which is separated by the addition of salt and comes to the surface in the molten condition. The glycerine is set free and remains dissolved in the spent lye. It is contaminated by the presence of salt used to render the soap insoluble. During the concentration of the spent lye for the recovery of the glycerine a large quantity of salt is thrown out, making the evaporation somewhat difficult, although this difficulty has been largely eliminated of late years by the use of properly designed evaporators working in vacuo. The final crude glycerine is a saturated solution of sodium chloride and some sulphate together with sodium salts of the lower fatty acids, in glycerine and water. The glycerine averages about 80 per cent and contains about 10 per cent mineral salts.

The glycerine refiner distills this crude soap lye glycerine with superheated steam in vacuo for the production of dynamite glycerine and chemically pure. The presence of so large a quantity of salt raises the boiling point of the glycerine and reduces its vapor tension so that the output is reduced. Furthermore, the salt accumulates in the still, producing finally a semi-solid mass of salt and glycerine, together with tarry matter which constitutes the "foots" of the glycerine trade. It is a difficult matter to extract all the glycerine from this residue without undue loss. The treatment of the "foots" is one of the problems of the glycerine trade.

The glycerine distiller, therefore, prefers a crude glycerine which is free from this large admixture of salt. Up to the early nineties all the crude glycerine refined consisted of what is termed saponification or candle crude. It was the by-product of the candle factory and was produced by the breaking up of fat in autoclaves by heating under pressures of 200 lb. and more with water and a little lime. The fat was split into fatty acids and glycerine directly and the latter was a product of considerable purity, containing about 88 per cent glycerine and less than 1.0 per cent of mineral matter. With the greatly increased demand for glycerine for explosives the soap makers, who formerly discarded their spent lyes, found it profitable to work them up, and to-day scarcely a soap plant can be found that does not recover its glycerine as a by-product. This change in the business compelled refiners to develop methods for distilling soap lye crude glycerine and eventually the larger refiners were working mainly on soap lye rather than candle crude, although there were still a number of glycerine refiners who worked exclusively on candle crudes. Saponification crudes free from salt have always been in greater demand and have commanded a higher price per unit of glycerine. For several years before the advent of the Twitchell process it looked as if saponification glycerine would practically disappear as a raw material in glycerine refining, but with the success of this process the Twitchell saponification crudes made their

appearance and are now a factor of very considerable importance.

The ideal of the glycerine refiner has thus been the production of a saponification rather than a soap lye crude by the soap manufacturer. It has also been the hope of the soap trade to obtain directly by the deglycerinizing of the fat a relatively pure glycerine as a byproduct and free fatty acids which could be combined with the cheap alkali, carbonate of soda, to make soap instead of the relatively expensive caustic soda. To meet this need have been developed the Twitchell process, the Krebitz lime saponification method and the Connstein ferment process.

The Twitchell process is characterized by its simplicity, and the low cost of the plant. Prior to Twitchell's discovery free fatty acids could only be obtained by the autoclave process involving a heavy capital outlay for copper apparatus which could only be used in small units and at a high temperature and pressure, making the operation expensive and somewhat dangerous. The autoclave saponification was used only in the preparation of fatty acids for candle manufacture, as the process was too costly to be used in the production of fatty acids to be used in soap. The Twitchell process is effected in loosely closed wooden tanks by digestion with water and as little as 0.5 per cent of the reagent and at a temperature not exceeding that of exhaust steam. The reaction may be carried out on a scale limited only by the size of the tank. The Twitchell process has made possible the saponification of fats on a huge scale for the direct production of free fatty acids and saponification glycerine. When combined with the distillation of the fatty acids for the improvement of their purity and color it has opened up for the soap trade the use of low-grade fats such as garbage grease and cotton seed oil foots, the distilled fatty acids being combined directly with carbonate of soda to produce light-colored soaps, and the glycerine being made available for the manufacture of dynamite glycerine. In this way the Twitchell process has benefited the glycerine trade in these days of glycerine scarcity by opening up new sources of supply, which were previously unavailable.

In Germany, Austria, Belgium, Holland and Scandinavia the larger soap plants prepare soap from fatty acids directly, and it is stated that in most of them the Twitchell process is used for the saponification of the fats.

The crude glycerine prepared by the Twitchell process comes to us from all parts of the world in normal times. There is no evidence that it is any less pure than the saponification glycerines prepared by other processes provided the fat used as a raw material is reasonably pure. Of course, a crude glycerine manufactured from a low-grade fat will fall behind a crude made from good tallow, but this is the fault of the fat and not the Twitchell process.

The Twitchell Process in the Soap and Candle Industry

By Martin Hill Ittner

It is essential in the candle industry to have a satisfactory method for separating the fatty acids, as such, from fats and oils. In the soap industry such a method, although it may be considered highly desirable, is not absolutely essential, since very satisfactory methods of direct saponification by alkali with the formation of soaps have long been utilized.

In recent years there has been an ever increasing demand for fats and oils and for glycerine, resulting in greatly increased market prices for these articles. The

market for soap and candle materials is directly related to the market for fats and oils for edible purposes, and an increased demand from either source usually results in higher prices for all fatty materials. High costs of fatty materials have made the practice of economy in the soap business essential. This economy may manifest itself in several ways. We will assume at the outset that the soap manufacturer wishes to maintain the quality of his products and therefore does not wish to make any sacrifice in this direction. His economy must therefore direct itself in one of the following directions: He must be able to utilize the fats and oils which give the greatest soap-making value at the lowest cost per unit, whether these materials are of the better or of the poorer grades, and he must so utilize his raw material that his final product will be of the same high quality no matter which grade is used. This means that he must have a method for getting good results out of poor material when poor material gives him the greatest value. It is also essential that he have some method whereby he may realize the maximum yield of glycerine at a low expense for recovery. This will readily be understood when I explain that at present market prices for fats and glycerine, which are both abnormally high, the value of the glycerine which can be obtained from one pound of neutral fat is about one-third of the cost of the fat. Another possible way of economizing is by quicker and easier methods of manufacture.

All of these advantages have been realized in some degree by the advent of the Twitchell process. This process has given a quick and easy method of obtaining fatty acids and glycerine from the better grades of fats so that the fatty acids are at once ready for making into better grades of soap, and the glycerine is in a condition suitable for easy refining. With care of operation the yield of glycerine may be made to approximate closely to that theoretically obtainable. When one operates on fats of poorer quality, and this may include black greases, the Twitchell process furnishes a most satisfactory method for saponifying. It renders the glycerine available even from such material and gives acids in good condition for refining by means of distillation. Such acids when carefully distilled yield a product of light color suitable for making good soaps of light color.

The use of fatty acids, as such, has made it practicable to use soda ash very largely in the place of caustic soda. The former will combine direct with fatty acids making soap from which the glycerine has already been recovered, whereas caustic soda is necessary for the direct saponification of fats into soap, and tedious methods must be used for recovering the glycerine, and, except with the greatest care, the yields will be poor. It will be thus seen that in the use of fatty acids a saving may be effected even in the alkali employed, as soda ash is considerably cheaper than caustic soda per unit of alkali.

Fatty acids suitable for making into soaps are also suitable for making into candle material. Partial solidification on cooling, will, with the aid of pressing, separate the solid from the liquid acids. The former yields commercial stearic acid so extensively used in candle manufacture and the liquid portion yields the oleic acid, or red oil of commerce. Red oil is used for many purposes, one of the most important being in the manufacture of soaps for washing wool. The manufacture of stearic acid and red oil did not originate with the Twitchell process, but the advent of the Twitchell process gave a new and satisfactory method for the saponification of fatty materials at atmospheric pressure with advantages over methods formerly used. Saponification by means of the Twitchell process may be carried out on a larger scale, with less danger and

with greater ease than is obtainable by other methods of acid saponification.

Twitchell's first process in which he recommended the use of sulpho-oleic acid was soon very much improved by the use of naphthalene along with the oleic acid during sulphonation. Whatever the chemical action in the formation of this reagent, it is my observation based on many experiments that satisfactory saponification will result from saponifier made as Twitchell recommends, whereas poor results only are obtainable when separate sulphonation and subsequent mixing are tried. I may say that I was among the first to have an opportunity to become acquainted with the process, and that this acquaintance has become closer with added years.

This process has been put to extensive use not only in America but also in European countries.

Twitchell later devoted himself to a method of manufacturing his reagent which would enable him to produce it in a more concentrated form. He accomplished this by methods of washing, extraction, precipitating as an insoluble salt readily convertible into an active reagent, and drying.

Twitchell and others allied with him have been busy in trying to still further perfect the process of atmospheric saponification of fats into fatty acids and glycerine with the result that a new sulphonated reagent with increased efficiency has lately been put upon the market.

The Twitchell process has been so simple in use that one is almost inclined to look upon it as nothing out of the ordinary. On careful thought one is forced to conclude that it is this simplicity which has become almost commonplace that commends it most to the many who have become familiar with it in operation.

An Appreciation

By Herman B. Schmidt

President Twitchell Process Co.

Thirty years is a span of life; practically a generation has passed. In these thirty years there have been in this country profound changes, unparalleled growth, and vast development. The bankers may tell you that the bank deposits have increased maybe ten times in this span of life. The iron people tell us the production of iron has increased about ten times. But what measure of increase can be put upon the developments that increased the chemists' opportunity—how many times? Surely a hundredfold at least.

Only a generation ago, when the industrial chemist started on a career, what had he before him? Simply the obligation to create an opportunity. As an example, going back to conditions then in Chicago, it was hard work to gather together a dozen men at a gathering. There were a couple of iron and steel chemists, two railroad chemists, a couple of metallurgical chemists, one soap chemist, one packing-house chemist, and a couple of assayers and a couple of professors.

The audience will get an idea of how inadequate the conception was of what a chemist's work consisted in. One day, in walking across the stock yards in Chicago, I was stopped by one of the then partners of what to-day is one of the largest institutions of its kind in this country, who said: "What do you do over at Fairbanks?" Explaining what the routine duties consisted of, what new things had been taken up by the laboratory, he finally said he did not think his institution could employ a man full time at that kind of work; and yet, three months after that interview, that institution employed its first chemist. I

dare say that that institution to-day has at least fifty in its employ.

In Cincinnati the conditions were similar, and if we look back on the chemist's equipment and temporary abode on a far-off lot, or prairie, with no gas, no electric lights, coal-oil lamps, and gasoline torches to work with, good work was carried on under severe conditions. I am always amused when I think of the difficulties of nitrogen determination at that time compared with the Kjeldahl method of to-day. Then we required a glass combustion tube and charcoal furnace and a boy to fan the coals. If he fanned too hard, the glass tube cracked; if he did not fan hard enough, the distillate was colored and you could not titrate it.

Under just such conditions our distinguished guest started.

In comparing these meagre facilities with the magnificent equipments that every college laboratory has to-day, I am reminded of Dr. Wolcott Gibbs who said when one day in his research laboratory the inadequacy of the equipment came up: "Why, do you know how the great Berzelius got his results? Why, all he had were some bottles, a sink and a cookstove. The present generation hardly realizes the huge advantages it enjoys."

Away out in a field, in a lean-to to a still building, Dr. Twitchell, too, had to create his opportunities, and there seeds of progress were sown. There were no fixed lines to work on; every step was capable of researches and these had to be made in order to find the ways in which the chemist could make himself valuable, and gradually the structure grew. Twenty-four years ago next July there was a meeting of the Society of Chemical Industry at Liverpool. One morning, while riding on the second story of a tram car (the two-story horse-car affair that was a characteristic of English streets) reading the itinerary of the meeting, a party slapped me on the back and said, "Are you a chemist?" "Yes." "Oh!" he said, "you are from the States. Where from?" "Chicago, but expect to go back to Cincinnati to live." "Well," he said, "Cincinnati; why, do you know Mr. Twitchell?" "Yes, we went to school together." "Well," he said, "he has made the best contribution to the chemistry of soaps that I know of. His method of determining the percentage of rosin in a soap is the only method that gives us the means of determining what a competitor has in his soap," and then my party said: "Here is my card, I am Dr. Lewkowitsch, and I had the experience of Mr. Twitchell's method in a soap works at Warrington." So our honored guest early in his career had made a valuable contribution to chemistry and was known to every chemist that was in fat and soap lines.

Only a few more years elapsed when Mr. Twitchell was able to announce the working out of the Twitchell process of glycerine recovery. The means employed were so novel that when the German Patent Office was asked to pass upon the patentability of the Twitchell reagent, they doubted that a compound described by Mr. Twitchell could exist. It is needless for me to dwell on what the process has done. You have heard that told to-night.

Just one more word. The young chemists will appreciate much more what Mr. Twitchell has done. His methods, employed in hundreds of factories throughout the world, have necessitated chemical control of operations and so have afforded just that many more opportunities for the employment of skilled chemists in those works. So what one man has done benefits one hundred or one thousand men through a new opportunity, and this is only one example of where the opportunity has grown a hundredfold.

Metallurgy of Cadmium—Raw Materials, Technique and Economics

By Franz Juretzka

Translated from "Metall und Erz" (12:235, 1915)

By Oliver C. Ralston

TECHNIQUE

As the result of the increasing use of metallic cadmium, the possibility of increasing the supply is of importance. In America especially of late the increasing production of cadmium is noticed. It was thought that the following notes would not be without interest to smeltermen and metallurgists.

Some of the common properties of cadmium, as compared with those of zinc, are as follows:

	Cd.	Zn.
Specific gravity	8.6-8.7	7.0-7.1
Melting point	325 deg. C.	420 deg. C.
Boiling point	750 deg. C.	900-1,000 deg. C.

The temperature of condensation is between 415 deg. and 520 deg. C. for both metals.

The principal ores from which cadmium is recovered are zinc blende and calamine ores. In the blende the cadmium is present as the isomorphous greenockite, CdS , not only in the regular sphalerite, but also in wurtzite. In calamine it is present as CdCO_3 . Usually the cadmium compounds impart a weak lemon yellow cast to the zinc compounds or products with which they are associated. The average run of blendes contains about 0.15 per cent Cd with considerable variations (Upper-Silesian blendes 0.15 per cent, Rhenish blendes less, Sterzinger blendes about 0.2 per cent and the Przibram ore up to 1 per cent Cd). Calamines are usually richer in cadmium. For example, Wiesloch (Baden) calamines contain 2 to 5 per cent Cd and Upper-Silesian calamines 0.3-0.5 per cent Cd and over.

The greater portion of this cadmium in the ore is lost during roasting and calcining and is found in an enriched form in the flue dust, but the latter product is rarely worked up for cadmium. Flue dust from blende roasting often contains 2.6 per cent Cd, usually in the form of the soluble sulphate. After leaching with water it is comparatively easy to precipitate it as CdS by the use of hydrogen sulphide. This CdS as a rule is contaminated with arsenic and can be freed from it by a slight roast. This leaves a brown cadmium oxide, CdO , as a starting point for the preparation of various cadmium salts.

The lithopone factories often have cadmium chloride in their raw ZnCl_2 liquors. It is precipitated by the use of zinc dust or by electrolytic means. (Dr. Alberti, Langelsheim, Harz.)

Most of the cadmium on the market to-day is made from the zinc dusts. Zinc dust contains 3 to 8 per cent Cd, according to the original content of the ore.

In the wet way cadmium is sometimes prepared by dissolving zinc dust in dilute hydrochloric acid, the zinc dissolving and leaving a residue of lead and cadmium. Some of the cadmium goes into solution and is reprecipitated by the addition of more zinc dust. This residue is later distilled to recover pure cadmium.

Although this method is very simple it is usually unprofitable. The zinc chloride liquor on precipitation with lime gives a zinc oxide which invariably contains some zinc oxychloride and later in distillation it is very troublesome. (As much as 10 per cent ZnCl_2 is retained by the precipitate.) It cannot be washed out and it is lost in distillation as it distills as ZnCl_2 , passing out through the prolongs, corroding the condensed zinc and making it of little value. The zinc dust is likewise rendered pyrophoric and unsuitable for commercial purposes. The costs of the zinc dust lost by reason of these

objections must be balanced up against the value of the cadmium obtained in the process.

As a starting point for the dry-process cadmium there is used the zinc dust evolved during the first one and one-half to two hours of distillation of a zinc ore. This dust often contains as much as 6-8 per cent Cd. The cadmium content of this dust is higher the sooner the prolongs are placed on the retorts after charging. It seems to be very important to be very quickly close and lute on the condensers and place the prolongs in position, after charging the retorts. It is also very essential that all of the dust should be well loosened from the walls of the prolong by pounding with a wooden stick during the process of collecting the dust, as the first dust tends to stick to the walls, due to condensed moisture.

By strict supervision it is possible to get seven to eight kilograms of dust from each prolong during the first one and one-half to two hours of distillation, and from a furnace with three tiers of retorts this means 20 kilograms of dust from each section. This zinc dust is mixed with about 50 per cent of its weight of carbon

FIG. 1—SHEET-IRON CASING FOR MUFFLES; MEASUREMENTS IN MM.

and placed in a retort of the kind usually used for zinc and distilled for about 22 hours at a dull red heat. In order to insure obtaining a yield of material rich in cadmium during this operation the prolong is removed when the flame issuing from it ceases to have a brownish tinge. For a condenser there is used a conical sheet-iron prolong (see Fig. 1), in which the cadmium, cadmium oxide and some zinc oxide collect. In order to prevent the walls of the condenser from being attacked they must be coated with whitewash and a rather thick coating of cadmium oxide allowed to form.

At the close of the distillation period the condenser is removed, cooled with water and then emptied into a special container. This material will contain about 75 per cent Cd. It is of a gray white color and feels soft and greasy when molten. If it is hard and dry it is a sign that the furnace got too hot and too great an amount of zinc was distilled. Under such conditions it is possible to stratify the material in the container by strong shaking, the particles of zinc tending to collect on the top, where it can be skimmed off and returned to the retort. The residues from the retorts,

FIG. 2—CAST-IRON RETORT; MEASUREMENTS IN MM.

which contain 45-50 per cent Zn, are returned to the zinc distillation furnace.

The cadmium metal made in this manner is mixed with about 40 per cent wood charcoal, or 60 per cent

of high-grade coke, moistened, and placed in cast-iron retorts (see Fig. 2) by the use of ladles and shovels, leaving the front portion of the retort empty for the collection of molten cadmium. The condenser is immediately put on and luted on with clay. Due to the fact that the opening in the end of the condenser is so

FIG. 3—CASING FOR RETORT, SHEET IRON; MEASUREMENTS IN MM.

small (only about 1 cm.), the gases first generated in the retort issue very quickly and may make necessary the repairing of the luting of the condenser. The design of the condenser is shown in Fig. 3, in which all dimensions are given in millimeters.

The molten cadmium collecting in the front of the retort is removed every four hours by the use of an iron ladle, in order to prevent its taking up too much zinc and iron. Every ten hours the condenser is removed, as a part of the cadmium boils in the retort and is caught in the condenser. During the emptying of the condenser the mouth of the retort must be closed with a brick of the proper shape. The condensed metal, which is usually shot through with little needle-shaped crystals, is dumped back into the forward part of the retort, the condenser replaced and luted on again. This also affords an opportunity to stir the contents of the retort well because the residues have a strong tendency to form crusts. Thirty minutes after the replacing of the condensers it is allowable to completely close up the exit opening in the condenser. Every morning the contents of the condenser are removed and then the retorts can be emptied.

The crude cadmium obtained in this way is removed and collected every ten days into a cast-iron kettle, where it is melted under a cover of oil and cast into

FIG. 4—CADMIUM MOULDS OF IRON WITH TWENTY-FOUR CHANNELS; MEASUREMENTS IN MM. THE CHANNELS ARE 250 MM. LONG

a mould of the type shown in Fig. 4. The sticks of metal are cut off from the "sow" by means of shears and are then ready for shipment. The dross is allowed to accumulate over a number of melts and finally is redistilled.

If the cadmium furnace is run too hot for a few days too much zinc will accompany it and even 0.5 per cent Zn is sufficient to alter seriously the properties of the cadmium. While cadmium of good quality gives sticks of good appearance, medium-grade cadmium gives sticks whose upper ends look dead. Inside these sticks are often some bubbles formed during casting, and on bending these rather stiff sticks they often break at the bubbles. The quality can also be told by the fracture of these sticks. Good

cadmium gives a brilliant crystalline fracture, while medium-grade cadmium shows a coarse-grained gleaming fracture and the poorer grades of cadmium give a fine-grained dull-gray fracture. Also a stick of good

quality cadmium will give a rustling sound much like the cry of tin when bent near the ear, while the poorer grades of cadmium will not do this.

In order to convert medium-grade into good-grade cadmium it is placed in the back of a warm retort in which a dam of sand is built, the cadmium distilling from the back end of the retort, condensing in the front end and in the condenser, and giving a high-grade metal with very little loss.

Table I.—Cadmium Production in Upper Silesia.

The Grasselli Chemical Co. is said to be recovering cadmium from cadmiferous dust and from a smelter fume. The American Smelting and Refining Co. is recovering cadmium from a fume in like manner.

The uses of cadmium are rather limited. It is used in the manufacture of Woods alloys, the composition being Bi 50 per cent, Pb 26.7 or 25 per cent, Sn 13.3 or 12.5 per cent and Cd 10 or 12.5 per cent, the melting pts. being 60.5 deg. C. to 70 deg. C.

In the United States it has found considerable application in the manufacture of fusible plugs in automatic fire extinguishing apparatus. One analysis is 50 per cent Pb, 27.5 per cent Sn and 22.5 per cent Cd. Lipowitz metal is similar to Woods metal and is often used by goldsmiths in soldering jewelry.

The amalgam used for filling teeth contains 26 per cent Cd and 74 per cent Hg. Cadmium is also used in the sulphide form for oil and china painting, as iodide and bromide in photography, as the chloride in colormaking and in calico printing. The sulphide is often used in coloring silk, and the sulphate is occasionally used for affections of the eyes.

ECONOMICS

If we assume that the dust from the distillation of zinc is collected for the first one and one-half hours after charging in a zinc smelter containing 30 furnaces of 120 retorts each, and that the dust contains 5 per cent of cadmium, and further, assuming the average figure of 20 kilograms of zinc dust from each furnace during this 1.5 hour period, and 900 furnace days per month, it can be seen that the production is $20 \times 900 = 18,000$ kilograms of zinc dust per month. This is 18 metric tons or 18 long tons of dust. The dust con-

sists of 5 per cent cadmium, and assuming 35 per cent recovery it is found that by reasonable care a 35 per cent yield is possible.

Forty to 50 per cent of the cadmium is lost during the enrichment of the dust and 20 to 25 per cent. remains in the residue. It is probable that the volatilization losses and the material absorbed in the muffles account for about 40 to 45 per cent. of the cadmium. Only 1.5 to 3.5 per cent of the zinc in the original dust is vaporized during removal of the cadmium.

If the recovery is 315 kilograms (696 lb.) of finished cadmium of 99.5 per cent grade each month, and if this sells for the average price of 7.75 marks per kilogram (84 cents per lb.) the total monthly receipts will be 2441 marks (\$581).

Against this income must be set the following costs:

	Marks	
1. For collection of the dust.....	90	\$22.40
2. Labor on cadmium furnace, 1 man during the day (30 days) 4.50 marks.....	135	32.10
3. Labor, part of one man's time at night.....	15	3.57
4. Disposal of residue.....	9	2.14
5. Nineteen ordinary muffles at 4 marks each.....	76	18.10
6. Twenty tons coal at 14.50 marks (\$3.46).....	290	69.10
7. Depreciation and amortization.....	50	11.90
8. Five per cent loss of zinc, at 5 cents lb.....	302	72.00
	967	\$232.31

So the net profit per month is 1474 marks, \$351.

The installation costs are as follows:

	Marks	
Furnace construction.....	1,000	\$238.00
Twenty condensers, at 5 marks each.....	100	23.80
One cast iron retort.....	150	35.70
Shears, molds, etc.....	250	59.50
	1,500	\$357.00

The life is calculated at about four years. This makes the rate of amortization per month 31.25 marks, while 50 marks was allowed in the above calculations. The iron retorts deteriorate more rapidly and the extra 18.75 marks is allowed for this purpose, although it only requires about 15 marks, leaving 3.75 marks for the necessary small repairs.

The cadmium furnace can easily be installed along one wall of the furnace room of the zinc smelter, causing very little change in the regular routine, and is as easily attended and served as the muffle tempering furnaces.

A plant of the above description would produce annually 3780 kilograms (8350 lb.), and at the above prices would bring in a net profit of about 17,688 marks (\$4,210). It is assumed that the zinc dust thus treated cannot be sold, due to lack of market or of some undesirable quality.

It can be easily seen that the making of cadmium should be very profitable business when cadmium is worth more than 7.50 marks per kilogram (81 cents per lb.). Furthermore the installation costs are low and it is easy to discontinue operations when the cadmium market is low. This is of particular advantage, and besides the small cadmium furnace is not injured in the same manner as a zinc furnace by being cooled off, and it can be easily converted into a retort tempering furnace.

Translator's Note.—Much of the metallurgy of cadmium above described is not new, and indeed a much better description of that subject is found in Ingalls' "Metallurgy of Zinc and Cadmium." However, the ease of recovery of cadmium and the small expense to which the capitalist is put in order to recover cadmium from zinc ores should be welcome news to American zinc smelting men. It is to be regretted that the commercial state of the art in the United States is such that it is very hard to get definite information on the technique of the metallurgy performed and on the present use of the product. It is known that others besides the Grasselli and the A. S. & R. companies are now marketing cadmium in the United States. Some of the A. S. & R. companies, as well as that of some of the other plants, is from the fine dusts of lead ores. Much of the present production would not be profitable, or at least would be much less profitable on 75c. cadmium. Hence the secrecy. It is to be hoped, however, that the technical advance will be such that more than 35 per cent recovery will be possible and that the number of producers will soon become such that information on the subject can be given out without imperilling the interests of the parties concerned. O. C. R.

New York Meeting of American Institute of Chemical Engineers

The sessions of the first day of the winter meeting of the American Institute of Chemical Engineers, held in New York City, from Wednesday, Jan. 10, to Friday, Jan. 12, were reported in our last issue. On Thursday an excursion was made to Perth Amboy, New Jersey, and in the evening a subscription dinner was held at the Chemists' Club. Mr. Maximilian Toch was toastmaster, and the speakers included Messrs. Olsen, Hendrick, Bakeland, and Baskerville.

On Friday morning a technical session was held at the Chemists' Club at which two papers were read. EUGENE E. AYRES, JR., of the Sharples Specialty Co., presented an able paper on "The Effect of Centrifugal Force on Colloidal Solutions." This will be printed in full in our next issue. In discussing the paper, Dr. Andrews asked whether with a solution containing particles of two different sizes, such as microns and amicrons, the removal of one size would not be hindered by the other; in other words, whether there would be a complete separation of a definite size when the force necessary to separate that size was applied. Mr. Ayres thought that in general a certain amount of another size would be carried down, but that it depended on the nature of the materials and on the electrical attraction of the particles. With some substances, a more complete separation of different size particles could be effected than with others. Dr. Richardson and Mr. McCue also discussed the paper.

The second paper was presented by Mr. CHARLES L. CAMPBELL, of E. B. Badger & Sons Co., who spoke in a very interesting manner on "Recent Developments in Distillation and Absorption." Publication of this paper in full is reserved for a future issue.

On Friday evening a technical session was held, at which the new president of the Institute, Dr. G. W. THOMPSON, read his address on "The Human Side of the Development of the Chemical Industries." The first part of this paper was printed in our last issue, and the concluding part will be found below in this issue. The paper was discussed by Dr. Frerichs, who spoke of welfare work done at his plant, especially in the matter of shorter hours, workmen's insurance, etc. He said the results obtained from better working conditions fully justified their adoption.

The second paper of the evening was read by Mr. F. W. SPERR, chief chemist of the H. Koppers Co., on the "Recovery of Benzol from Coke Oven and Illuminating Gas." This paper is printed in full on page 135 of this issue. In discussing this paper, Dr. Frerichs mentioned a distilling column used in Germany which was filled with short cuts of pipe of different diameters, as, for instance, 1 in., 2 in., and 3 in. The cuts are about as long as the diameter. A well-known manufacturer of carbolic acid in Germany has used this column with success, and a much shorter column can be used. Mr. Sperr said there was a tendency to make the column more simple, and to place more dependence on the dephlegmator. Mr. Campbell said he was familiar with the system, but not from actual experience with it. He thought it quite possible that this short column, filled with cuts of pipe, would give the same

results as a long one with plates. Mr. Peterson asked whether it was possible to recover benzol from producer gas. Mr. Sperr said he had examined one producer and did not find enough benzol to warrant commercial recovery. The possibilities of recovering ammonia, however, are very great. In the by-product coke oven about 25 lb. of ammonium sulphate are recovered per ton of coal used. It is possible to recover from 80 to 85 lb. of ammonium sulphate per ton of coal used in the gas producer.

The last paper of the evening was by Mr. ANDREW M. FAIRLIE, on "The Fairlie Method of Control of the Chamber Process for Making Sulphuric Acid." This was presented in abstract by Dr. Olsen, as follows:

The deficiencies of the old methods of controlling the chamber process are pointed out, and the Fairlie method is described. The latter

G. W. THOMPSON
President American Institute of Chemical Engineers

(technical description in U. S. Patents Nos. 1,205,723 and 1,205,724) has been in continuous daily use at the plants of the Tennessee Copper Company for six years. It consists in determining the percentage of sulfur dioxide in the chamber gases at some point near the front end of the chamber system, and in comparing such percentage with the percentage sulfur dioxide in the burner gas, before admixture with niter fumes. The comparison shows, after experience, that a certain ratio between the two sulfur dioxide percentages must be maintained in order to secure the best results in the Gay-Lussac tower. What this desirable ratio is must be determined for every possible grade of burner gas. Once determined, the desirable ratios are arranged in tabular form on a card, which is framed and secured in a place convenient for reference by the chamber operator. This operator, by taking tests frequently of the burner gas and the front chamber gas, obtains accurate information as to the speed of oxidation of sulfur dioxide in the chambers, and obtains this information in time to apply the proper remedy and to adjust correctly the proportions of niter admitted to the process, whenever anything is about to go wrong.

The usual analytical method for the determination of sulfur dioxide is altogether unreliable as applied to gas mixtures containing the oxides of nitrogen. An improved method has been devised, and this method is described in detail. Without this improvement in the method of determining the sulfur dioxide in chamber gases, the development of the new method of chamber control would have been impossible.

The Human Side of the Development of Chemical Industry*

By G. W. Thompson
(Concluded from page 81)

I think that I have said enough along this particular line to indicate to you my views as to what the chemist should do in the direction of trying to develop a popular appreciation of his work. If there is truth in what I say I am quite sure the open mind of the average chemist will discover it. If I am wrong he will soon find the vulnerable point in my argument. I would like now to pass to another aspect of this question, which relates more particularly to the chemist himself. What I have said so far deals for the most part with the attitude of mind of the chemist toward the public. What I propose to say now deals with the attitude of mind of the chemist towards himself. I have referred to a relation existing between the chem-

*A paper read at the Ninth Annual Meeting of the American Institute of Chemical Engineers, New York City, January 12, 1917.

ist and the public. In this relation there are two parties, the public on the one hand and the chemist on the other. The problem before us is: What should the chemist do to develop and improve his attitude of mind towards himself? This is an exceedingly difficult subject, and if it were not that I am fortified by a belief in its importance, I would not dare to speak upon it. I cannot think of anyone holding a higher opinion of chemistry as a profession than I do, and all that I am saying is actuated by a profound belief that the chemist is only beginning now to climb the ladder that reaches to a power of service unequalled by any other profession.

The delicacy of this subject is such that I feel impelled to approach it in the form of questions. In putting these questions, let us consider first some facts, and then we can come to the questions themselves. Let us first consider the young chemist just leaving his college or university. Like all students graduating in various courses, he has yet to learn what business life really is. They think they know what it is, but we know that there is no college or university that teaches it. The difference between the chemist and most other graduates is noticeable in this: The chemist enters a more or less isolated laboratory; most of the others go directly into the commercial world. The chemist in this laboratory—be it analytical or research—is not dealing with people, but with inanimate material things. He may stay in this laboratory a few months, a few years, or for his lifetime, as the case may be. He may be doing invaluable work, but—here is the question: Is he taking his proper place as a man in the world of men? Is he not too much isolated? Is he in his occupation gaining directly in his power over other men? Is his social instinct being developed or is it being retarded in its growth?

If we think that laboratory chemists as a general class are taking their proper place in the world in which mind reacts upon mind, there is nothing more to be said; but if we think with his intelligence and education, the chemist has a mission outside of the indirect service he professionally renders to society, then our question leads us to urge that the barriers which ordinarily isolate the laboratory chemist should be broken down so that he can get out more into the pulsating business world. He may not be able to do this alone, and perhaps the duty devolves upon us; perhaps there are some of us who have it in our power to help bring about this liberation. If we want chemists to have a greater personal influence in the world, and by this we mean to include those chemists who are subordinate to us individually, is it not proper for us to ask ourselves whether at times we do not rather selfishly stand in their way? Cannot those of us who are employers of chemists give our employees more opportunity to become familiar with the commercial aspects of the work they do? If we do this, will they not become better and more profitable employees? In our dealings with non-technical men representing large business interests, could we not more regularly and persistently ask to be brought into contact with their chemists if they have them, thereby helping to pull them out of their seclusion? If we are asked to organize a laboratory in a commercial concern, could we not say that the work of the chemist would be greatly helped if it were so arranged that he would know the actual use to which his reports were to be put? Could we not do something in urging that the laboratories in which such chemists are expected to work should not be hidden away in inaccessible places? Could we not do many things suggested by the occasion to break the bonds which the young chemist, led by false hopes, may have often slowly forged? Is it not possible that with our col-

leges to-day filled with students of chemistry, these students should be advised against accepting positions of an isolated character?

You will see that I am basing my argument on two hypotheses, which are intimately related. One is that social relationship is one of the great purposes of life, and the second is that without such social relationship no individual can really be successful in the development of any important enterprise. I have argued, therefore, that the chemist's success depends upon a social recognition of his worth, and second, that the chemist should enter into as broad social relationship as possible. In popular terms one of these means that it pays to advertise, and the other means that the chemist should get out upon the broad highway.

I propose now to say a few words on the disadvantage which is sure to result from antagonism. I propose to advocate in all our dealings a conciliatory spirit. It would seem almost unnecessary to say that if the chemist is to advertise, he should avoid offending the persons who read his advertisements, just as it is perfectly obvious that the salesman who is trying to sell goods should not make himself *persona non grata* to the purchaser. A good salesman—and that is what we should all try to be in one form or another—subordinates his own views and makes them as inconspicuous as possible, but no less effective. What he tries to do is to find out the views of his customer so that he can furnish the customer with what he desires. I wonder if sometimes chemists are not a little more pugnacious than they should be. I sympathize with the feeling of an analytical chemist who will set his results up against the world and insist that he is right, but many years of experience have taught me that the chemist who does this without regard for the effect upon other chemists is doing a very foolish thing. I believe it is a good rule never to put anybody "in wrong." I believe it is far better, even in the case of commercial opponents, to help the commercial opponent out of his difficulties rather than to push him in deeper. Again, are we not at times a little too virulent in asserting our ideas respecting public officials—administrative, legislative and judicial? They are human beings just as we are, they are representatives of the whole people, and if their views differ somewhat from ours, is it not very much better to work patiently and steadily to change their views, directing them into constructive paths, rather than to confirm them in their views and drive them to unwise extremes by opposing them vigorously?

Let us take as an illustration a subject on which perhaps chemists are divided at the present time, although the division may be by no means equal. Many chemists are seeking to have our national government help the chemical industry to become more firmly established in this country. Some think it can be done by subsidies, others by protective tariffs, others by embargoes, and so on. Now I would not argue in this meeting for or against any of these propositions. I simply say that if you are in favor of any one of them it is unwise because he opposes you to incur the antagonism of any public official, even if he be of an opposite political faith. Practically all public officials have their ears to the ground; they are trying to find out what their constituents want, and no one should blame them for this. In so far as they are representatives they are only doing their duty. It is perfectly proper for us to try to convert a public official to our way of thinking. It is still more proper for us to try to convert the people he represents to our way of thinking, but I consider it the height of foolishness to attribute to public officials dishonest purposes, ignorance, stubbornness and all the other sins of commission and omission. My

point is very clear—such accusations do not lead you anywhere but into trouble.

I believe firmly that the obstacles which we meet in our social acts in endeavoring to get our plans consummated do not differ essentially from the obstacles which the chemist meets in the ordinary routine of his work. If he finds a chemical reaction is not progressing satisfactorily, he does not close his eyes to this fact and denounce some devil or anthropomorphic god because it has interfered with his work. He tries to find the cause of the trouble and remove it. So I say that if you have social obstacles to overcome, find their cause and remove it, bearing in mind that there is no easy way by which this can be accomplished—in fact, that there is only one way—education backed by good-fellowship.

We have heard in recent years a great deal said about efficiency; it may be that some foolishness has been uttered. The word "efficiency" is used in various ways. We have the efficiency of a process considered by itself; we have this efficiency as compared with other processes; we have mechanical, chemical and human efficiency. I am interested primarily in this paper in human efficiency. What does it mean? Broadly speaking, it means co-operation without friction. Perhaps we should say that co-operation cannot be had with friction. Of course, it would be absurd for me to attempt to solve the eternal problem of human friction in a paper of this kind. All I can do is to indicate some ways by which it can be reduced. While the realization of frictionless humanity is far away, symptoms of it have certainly appeared at times. Efforts in the direction of reducing human friction conspicuously numerous at this time are to be found illustrated in factory welfare work, workmen's compensation acts, pension systems, etc. All of these have been justified by the increase in human efficiency they have produced. A man whose welfare is of no account is not a good workman.

Human efficiency, however, demands right men in the right places. The difficulty that the employer experiences is in knowing whether he is picking the right man for the place or not. If the man has been educated rightly the employer is better able to form an opinion. Particularly is this true regarding foremen and the higher grades of labor. Graduates of such institutions as give technical education are made more nearly right for places in chemical and other industries. More general industrial education such as that being advanced in some states will undoubtedly add to human efficiency. Even then the making of a man suitable for a given position comes after he commences employment and is largely the work of the employer himself.

Industries do not merely require men, however; they are complicated machines of which the men form a part. The proper fitting and adjusting of these machines to the men employed is the big problem only partly worked out as yet. Each industry has its own requirements, these requirements continually changing with the growth of society. Who has not been face to face with the requirements of an industry? These requirements are almost vitalized by competition. Industries come and industries go, they are planted and they are reaped, but their volume increases from year to year. We must not, however, allow ourselves to think of industries and industrial processes as though they were other than inanimate things. We should not waste our tears over their rejection when they are worn out, provided others take their place. This is growth—the sloughing off of the old and the putting on of the new.

The chemical engineer has a great deal to do with the development and administration of new processes.

Many an old foggy has damned the chemical engineer, who has rendered his processes and his equipment antiquated and idle. The mechanical engineer also has received his malediction. We are sorry for the old foggy and would, if it were possible, provide insurance for him, but we would do nothing to retard the fate of his equipment.

The development of a new process is the result of many separate factors. New processes are like the waves of the sea—they cannot rise much higher than the level of the sea itself. They rest on general industrial growth and are not much above the level of that growth. This is true of all processes, chemical processes included. Their growth depends upon the growth of the mechanical art, its methods of fabrication, and all the materials that enter into construction. It depends upon highly developed foundry practice, mining, building construction, farming and transportation, and last, but not least, all those branches of human development which are manifested in the home, social organization, governments and international relations. I emphasize this human factor because so many processes have had to wait years for the time to ripen for their introduction, indicating, in other words, that not alone should our endeavors be directed to the development of processes, but they should also be directed in a general effort to accelerate the coming of the fullness of time. The fullness of time means that the social level has been sufficiently raised.

New processes are of two kinds: First, those which provide improved methods for making old and well-known products, and second, those which involve the making of new products to take the place of old, or new products which serve entirely new purposes. A new process which is intended to provide methods for making an old product, if it is to be successful, must involve economy of some sort—economy of material, investment, time or labor. Necessity creates the demand for such new processes. Competition, domestic and foreign, is the impelling force. The wise manufacturer recognizes that the development of a new process may be his salvation. It is impossible in this paper to discuss all the demands which compel the invention of a new process. We will discuss only the human or labor element.

If labor here in the United States is higher in price per unit of product than it is abroad, it is manifest that with free competition the manufacturer must so modify his process that this item in cost will not militate against him. He may not be willing to modify his process, and his first instinct may be to limit the competition by a protective tariff or some similar restrictive measure. One objection to this, except as a last resort, is that it removes some of the pressure which makes for improvement of process. We may dislike the pressure, but we know after all that it is a good thing. We cannot allow anything to interfere with such pressure as makes improvement necessary. Such improvement may be possible. It is much wiser to insist that it is possible than to insist that it is not. Success is often accomplished by doing what is apparently impossible, but assuming that the manufacturer cannot get the protection he wants, how will he go about improving his process? We will offer only a few suggestions.

The first consists in manufacturing in large units. By this means overhead charges are reduced and materials can be handled more cheaply by mechanical means, thereby either directly or indirectly reducing the cost of the labor factor. In this direction it would appear that the United States has been pre-eminently successful; there is probably no country in the world which

equals us in this line of development. The second consists in subdivision and specialization of labor. It is obvious to all that it is through this method that most of our industries in his country have been successful. The third is radical development of process. If we take a given process and consider all of the operations, step by step, we are able tentatively to classify these steps into two kinds—the essential and the apparently necessary. The apparently necessary step is not by any means an essential step. An apparently necessary step is one that the state of the art has not eliminated. An essential step is one that we feel justified in saying cannot be eliminated, no matter what the state of the art is. By a radical development of process it may be possible to eliminate apparently necessary steps. The burning down of a house in order to roast a pig was in the mind of the Chinaman of fiction an apparently necessary step. It was, however, eliminated by the efficiency engineer of his day. Fourth, by doing by machinery what was theretofore done by labor. An essential step in a process may still appear essential, although instead of performing the step by manual labor it is done by machinery. This much does not involve the elimination of a step. Doing by machinery what was theretofore done by labor is the obvious method of reducing labor costs. It usually entails, however, additional cost for investment, power, and repairs, and also the employment of a higher class of labor. It is perfectly obvious that where labor is cheap machinery is unnecessary, but that where labor is high competition compels the use of machinery, and that this is the proper and natural order of things.

This is perhaps to you a somewhat academic presentation of the methods to be followed in studying how a process can be improved. If I should go into the methods by which new processes for making old or new products might be worked out, it is probable that this study would be still more academic, and I will not attempt here to touch upon that branch of the subject. What you may consider academic in what I have said, however, has a very practical bearing upon the general subject I am endeavoring to present. As I have already indicated, I am interested in human efficiency. Mechanical efficiency that does not lead to human efficiency is of rare occurrence. Considered in the most general economic terms it is doubtful if it ever occurs. It is natural for us to think of human efficiency as a means rather than an end, but I would reverse this relation and ask you to consider human efficiency as more of an end than a means. It is desirable that we should have high-priced labor because high-priced labor usually means greater intelligence and higher character.

A more highly developed social organism is one of the noblest objects for which one can work, and all efforts spent on the development of its parts is well worth while. If you believe with me that an appreciative public is necessary for the proper growth of the chemical industry, you will also agree that we need a public which shall have the power of appreciation which can only come as a result of the general raising of the level of social conditions.

The chemist by working for improvements in processes involving a saving of labor, and at the same time involving the employment of a better grade of labor, is contributing his part to the better development of a high social organism. If the chemist, however, simply endeavors to improve a process without regard to the possibility of that improved process involving the employment of a higher type of labor, then his work is incomplete. It is true that his process may with cheap labor be able to manufacture products which are used by the entire community, and which consequently can

be sold at a reduced figure and thereby benefit society, but many difficulties will lie in his path if he does not at the time that he reduces the quantity of labor necessary in the process also create a demand for a higher quality. I therefore ask those of you who are engaged in the development of processes, such development being forced by competition and the requirements of the industry, to consider whether it would not be better for you to put your mind in the attitude that in your development of process you may possibly be able to get better results by the use of more intelligent and higher priced labor than you could by sticking to low-priced labor and possibly handicapping yourself and your process and preventing its fullest development.

I have endeavored in this paper to present several aspects of a very large and important subject. Some parts of it may appeal to you and other parts may excite your opposition. In the main, however, I believe all of these parts are related to each other consistently and logically. If you believe as I do, that a better social organism is the highest purpose for which anyone can work, you will accept what I have said and include in the proposition many extensions on which I have not touched. If, however, your minds are more practical, I think you will accept many of the things I have presented to you purely on account of their practical value. Therefore from whatever standpoint you approach the subject, am I not correct in stating that practical business success in all lines of business, including those involving the use of chemistry, is dependent upon popular appreciation, is dependent upon social growth, on which the power of appreciation rests, and that everything which tends to increase the power of appreciation helps appreciation itself, and that anything that increases appreciation increases the chance of success of a business enterprise. Or to put it negatively, anything that interferes with an increasing power of appreciation, anything that tends to prevent appreciation or creates those antagonisms which operate against appreciation is pretty sure to hinder the growth of a business enterprise.

If this fundamental proposition is accepted, we can readily see how important it is for the chemist in attempting to build up chemical industry in the broad sense to do everything in his power to raise the general level of human knowledge and education and of social conditions, for it is that level that determines the power of appreciation. Assuming this power of appreciation to exist and to be growing in strength, you will also, I think, agree with me that the chemist should do everything in his power to create a greater appreciation of the value of chemistry in solving the problems of industrial life, for it is only through such appreciation that the chemist himself will be able to exert fully that ability for service which we all believe he possesses. But if the chemist is to impress himself on the public through legitimate advertising, should he not also endeavor to develop that attitude of mind which makes him continually a factor in social growth? Should he not break away from all influences that tend to isolate him, and that, if they do not make him a peculiar being, at least have the effect of preventing him from having the fullest influences over others? Should we not do everything in our power to broaden the horizon of the chemist, to increase, as it were, his circulating power in the social organism? Should we not, as chemists, by very simple methods do all we can to pull chemists individually out of all such surroundings which tend to narrow and handicap them?

Now having done all of these things, should we not go a step further and recognize the peculiar position which the chemical engineer occupies in the develop-

ment of chemical processes? Our minds naturally operate discontinuously. We think of a chemical process and its development as an independent thing, as though it were not a part of all of the other processes continually operating in society. We think that with the development of a process our work is ended; we think that with cheaper manufacture of given products we can sit down with satisfaction and consider our efforts successful. But philosophers tell us that there is no such thing as discontinuity, that everything runs into everything else continuously and is a part of a complete whole. Some fancifully have said that if a man could destroy a single atom, the universe would fall to pieces. This is fanciful but it expresses a true conception. There is such a thing as solidarity—not the solidarity of labor, not the solidarity of industry, but more surely the solidarity of society. All things operate in circles. We have continuous production and continuous consumption, in which material things circulate around and around, never completely stopping. This is so of all human affairs. Effects are unending. All the ends we work for are but the means to other ends. The development of a process was the end yesterday, but to-day it becomes a means—a means by which the social level is raised, which in its turn becomes a means by which other processes are developed.

This is why I have expressed my opinion that in the development of a process it can hardly ever be said to be complete unless it results in the substitution of quality of labor for quantity, whenever such a development has for its purpose the saving of labor. Development of a better quality of labor is essential if we are seeking broadly to increase the power of appreciation on the part of the public. It would be manifestly foolish for me to advocate that chemists should seek to impress Hottentots and Fiji Islanders with the power of service in chemistry. It would take centuries of education to bring them up to the point where we of America are to-day. It is equally foolish to think that we can expect as much appreciation from common labor as we can from intelligent labor. In saying this I make the assumption with which I hope you will agree—that every member of society, the ignorant and the wise, the poor and the rich, the bad and the good, the sick and the well, are all integrally a part of society, and each one has his individual influence in determining the average social level which measures the power of appreciation.

I have endeavored in this paper to avoid taking any position which is negative in its character. I do not believe that there is such a thing as a negative force; the nearest we come to it is inertia. I have endeavored to make positive suggestions which I submit for your consideration with the daring hope that these suggestions may find lodging places, temporarily it may be, in your minds, and if, after these ideas have stayed in your minds for a short time, they then take their flight, I have the still more daring hope that after you have forgotten them they may, though unconsciously to you, have left some faint imprint.

Volatility of Gold at High Temperature in Atmospheres of Air and Other Gases*

BY W. MOSTOWITSCH AND W. PLETNEFF

In the experiments to be described gold was used which was produced and purified by a modification of the method of Krüss (Liebig's Ann. 1887, vol. 43, p. 237). The gold was precipitated from a desilvered solution of Au Cl₃ according to Vanino and Seemann (Berl. Ber. xxxiii, 2, 1908) by means of H₂O₂ and KOH,

*Translated in abstract from the Journal of the Russian Metallurgical Society, 1915, No. 3, pp. 410 to 431.

washed and melted under borax. The experiments were conducted in a horizontal Heraeus furnace.

In the preliminary experiments 355 to 530 mg. of gold were fused for 30 minutes at temperatures up to 1400 deg. C. in an unglazed porcelain boat (which weighed 2g. and had been heated to 1300 deg. C.) in streams of dry gases of air, CO₂, CO, N₂ and O₂. The amount of gas used was in all experiments 800 cc. The volatilization was determined from the loss in weight of the gold.

The loss of gold in a stream of air was observed only by previous weighing and weighing at each temperature. The results of the tests, which were carried out at temperatures of 1100 deg., 1150 deg., 1200 deg., 1250 deg., 1300 deg., 1350 deg. and 1400 deg., are given in a table in the original Russian publication. From the tests the gold was found to undergo no loss, on melting at 1150 deg. C. for 1.5 hours, at 1200 deg. C. for 2 hours, at 1300 deg. C. for 3 hours, at 1350 deg. C. for 1 hour, at 1400 deg. C. for 2.5 hours in air.

In the experiments made in streams of O₂, N₂, CO, and CO there were no losses found up to 1400 deg. C.

In the final experiments, which were more accurate, the gold was in a chip of a quartz tube (pyrometer protection tube) which weighed 0.2 to 0.3 gram. Weighings were made on a delicate balance by means of a microscope. The gold, quartz chip and silica boat were weighed exactly, before and after heating. The gas was conducted through the furnace at a pressure of 2 to 3 mm. Hg. For each temperature the quartz chip with the gold was kept in the furnace for exactly 30 minutes.

Experiments with O₂, N₂, CO₂, CO.—Only in the first melting was a loss observed, which was caused by the gas content of the freshly prepared gold being weighed. Otherwise, between 1250 and 1400 deg. no volatilization was observed.

According to T. Rose (Metallurgy of Gold, 1906, p. 6. and Journ. Chem. Soc., 1893, lxiii, 714) this loss is considerable.

Experiments in a Stream of H₂.—Thirty tests were made in an atmosphere of hydrogen; some in purified hydrogen from a cylinder and others in hydrogen obtained from pure zinc and sulphuric acid. Up to 1100 deg. no loss was observed. From 1200 deg. on volatilization began and the loss increased with the temperature and duration of heating. The results from one series of tests using 400 mg. Au are as follows:

Temp.	Duration of Heating	Loss in Mg.	Per Cent Loss
1,250 deg. C.	25 minutes	0.2	0.055
1,300 deg. C.	25 minutes	0.35	0.090
1,350 deg. C.	25 minutes	0.42	0.105
1,400 deg. C.	25 minutes	0.98	0.250

If a curve is plotted illustrating the relation between volatility (as ordinate) and temperature (as abscissa) it will be found to rise quickly from 1350 deg. C. on. The quartz chip which contained the gold, the silica boat and the heating tube were colored an intense red, while with all other gases no color was observed. A colloidal solution of gold in quartz is formed ("ruby-glass"). In the absorption liquid (H₂SO₄) gold could be determined qualitatively.

CONCLUSIONS

1. Chemically pure gold is not volatile in atmospheres of pure air, O₂, N₂, CO or CO₂ at temperatures between 1100 and 1400 deg.

2. Chemically pure gold is volatile in hydrogen. The volatility becomes noticeable at 1250 deg. and increases with the temperature and duration of heating. What is the cause of this volatility in hydrogen? Is it a result of direct vaporization of the gold, or is it caused by the formation of a volatile compound of gold and

hydrogen? If the gold is directly vaporized, then we could also observe this phenomenon in other gases. The experiments in air, O_2 , N_2 , CO and CO_2 did not show this.

There remains the supposition that gold forms a volatile compound with hydrogen, AuH_x , at temperatures over 1200 deg. This is unstable and breaks up into $H_2 + Au$. From this the characteristic coloring of the quartz boat, tube, etc., can be explained, which is connected with the formation of a colloidal solution of the gold in the quartz or the ruby glass. This is the more probable when we consider the analogous phenomena with copper. By continued heating of copper in hydrogen, Leduc (Comp. rend., 1891, xciii, 71) observed the formation of the hyacinth red compound Cu_2H_2 , which was partly volatile. This explains also the red coloring of the refractory glass tube in which copper is heated in hydrogen in order to purify the latter from oxygen. In addition, we know a series of metals which form volatile hydrogen compounds, for example: Sb, Ba, Ge.

Tomsk, Russia.

Development in Chemical Engineering Equipment*

By H. D. Miles

President Buffalo Foundry & Machine Co.

As it is impossible in the time at my disposal to adequately describe the development of chemical engineering equipment, I shall only briefly review some of its more important phases as they have come under my observation in the manufacture of chemical equipment by the Buffalo Foundry & Machine Company, of which company I am the president.

This company was organized sixteen years ago on what at that time was considered a radical departure, namely, the operation of a modern foundry on a scientific laboratory-controlled basis. At that period the large majority of foundries were operated by rule-of-thumb methods, and no attention was paid to the chemical composition of the metals used. Metal mixtures were made on a grade basis, known as Nos. 1, 2, 3, and 4, gray forge, scrap iron, etc., the grade being determined by the appearance of its texture rather than by its chemical composition. Very little attention was paid to the percentage of different elements contained in the iron. Frequently what appeared to be a high-grade No. 1 pig iron would, when analyzed, prove to be an inferior grade.

This laboratory control established a reputation for quality and accuracy, and chemical castings, demanding the highest developed standards, immediately became one of our principal products.

It is now fourteen years since we entered this field, and for an active beginning joined issue with European manufacturers who were exporting into the United States the large pots used by caustic manufacturers, and who largely dominated the American market as the domestic product was inferior. After careful research and development, assisted by the co-operation of our customers, we were finally able to produce caustic pots of a better quality, that is, giving longer life, than those being imported from Europe.

We next turned our attention to chemical retorts of one type or another for handling different acids, and to acid eggs, and acid kettles, and ultimately obtained equal results in the manufacture of these.

After our success with these lines of chemical equipment, and several years before the outbreak of the present European war, we entered the field as manufac-

turers of vacuum dryers, pumps, and condensers, which apparatus has to-day so wide an application in the chemical field. We developed a full line of vacuum dryers, consisting of shelf dryers, rotary dryers, drum dryers, and vacuum drying and impregnating equipment, as well as the auxiliaries which go with such apparatus, namely, vacuum pumps, condensers, expansion tanks, reclaiming devices, dust collectors, etc.

This equipment, which we have highly developed with new and patented devices, is especially useful where rapid drying free from atmospheric variations is required, or where in order to avoid injury to the materials under treatment, drying must take place at low temperatures.

In this connection I wish to call attention to our vacuum drum dryers, which are constructed to dry in large quantities and at low cost without practically any loss of material, emulsions, pulps, extracts, white lead, glue, milk, acids, dyes, and other liquids containing solids. These liquids are reduced to dry forms economically and quickly and without danger of injury to the quality of the material.

We have so far manufactured five sizes of vacuum drum dryers, the smallest having a drum 2 ft. in diameter by 20-in. face, the largest 5 ft. in diameter by 12 ft. face. All sizes are so constructed that they may be easily cleaned and kept in sanitary condition, which is a vital consideration when handling food products. The smallest dryer is so constructed that the casing over the drum can be readily moved back on a track so that free access can be had to all parts of the interior. The larger types are so arranged in size and convenience that a man can enter the casing and scour all parts of the interior.

Our patented method of applying the liquid to the surface of the drum is the result of many developments in our particular machine, and the present arrangement assures a very uniform coating on the drum as well as a large output. There is a large reservoir in the bottom of the casing for holding a considerable quantity of material to be dried. This material is taken, as required, by a circulating pump located beneath the dryer and delivered to a supply pan immediately under the drum and slightly in advance of the knife or scraper which removes the material. Only a small section of the drum surface comes into contact with the liquid

FIG. 1—VACUUM DRUM DRYER

*A paper read at the New York meeting of the American Institute of Chemical Engineers on January 10, 1917.

material and, therefore, over three-quarters of the drum surface is active at all times in drying. The material is forced in the pan under sufficient pressure to insure a uniform coating on the drum. The extra supply of liquid, which escapes on the side of the pan where the film comes out, overflows into the reservoir in the bottom of the dryer. By the time the material reaches the scraper it is dry enough for removal. It is automatically scraped from the drum, falls into a conveyor, and from there is removed to a receiver. Two receivers are used, one on each end of the machine. While one is being loaded the other is unloaded, an arrangement which permits the machine to be operated continuously.

Where the drum dips into the main body of the liquid, it is impossible, owing to the agitation and foaming of the liquid, to always maintain a constant level of the liquid material. This constant change in level results in an irregular immersion of the revolving drum surface, with a consequent variation in the moisture content of the dried product, loss of continuous service, low output and heavy cost of operation.

With our method the drum does not come into contact with the main body of liquid and, therefore, any material can be dried satisfactorily whether it foams in a vacuum or not. It is also to be noticed that as some materials give over their moisture more readily than others, the speed of the drum, and the pressure of steam used in the drum, can be varied to suit the material being treated.

One of the most extensive uses for the "Budlovak" vacuum drum dryer has been in the production of powdered chestnut and hemlock extracts. Formerly, these extracts were put on the market in a liquid state, containing approximately 50 per cent moisture. They were shipped in tank cars. These materials, with this moisture content, can be treated in our machine and dried to a powdered form, having from 5 to 7 per cent moisture content. This dried material can be packed into bags and shipped in this manner to any part of the world. By handling it in this form the market for the material is not only very much widened, but the expense and trouble of tank cars is eliminated, and consequently transportation expenses greatly reduced.

Another important use for this machine has been developed in the recovery of dry sulphite waste from the waste liquors of paper mills. This product, owing to its recovery in a dry state, now brings a handsome profit to the paper mills, and secures another by-product that can be converted to many useful purposes. It further enables the paper mills to comply, actually at a profit, with the laws prohibiting the pollution of streams with sulphite waste.

The approximate capacity of our 5-ft. by 12-ft. vacuum drum dryer on the above mentioned extracts and sulphite waste is 1000 lb. of dry product per hour. The cost of operation is extremely low. We have dried products where the cost, including depreciation and interest on investment, steam, power, labor and incidentals, has not exceeded one-tenth of a cent per pound in reducing a product from a 50 per cent moisture content to a commercially dry product under a 7 per cent moisture content.

Vacuum shelf dryers and vacuum rotary dryers have also been extensively used in the recent chemical development in this country. They can be used to great advantage in drying some of the chemicals derived from coal-tar distillates. This use is in addition to their previously extensive application in the drying of both liquid and solid materials. These dryers are also especially valuable in handling solid materials, the shelf dryer for drying sheet rubber, fruit, albumen, etc., and together with the rotary dryer, is available for use in

drying reclaimed rubber, rubber compounds, paints, dyes, extracts, pastes, glue, soap, salts, starch, vegetables, etc. Where the quality of the material is not affected by being tumbled or mixed while drying, or is not of too sticky a nature, the rotary dryer is an ideal apparatus for drying in large quantities.

At the outbreak of the present European war, when the supply of many materials never made in America was cut off, there was a sudden and large demand for chemical equipment, particularly in plants handling the many products produced from coal tar. In order to meet this demand, it was important to first make use of apparatus developed for these purposes in Europe. It was also essential to design new types of apparatus to suit conditions in this country and to make modifications in equipment which had been developed abroad.

The Buffalo Foundry & Machine Company, to its already well established engineering and consulting staffs, at once added a corps of experienced specialists who, with the co-operation of chemical engineers associated with chemical plants, developed machinery to manufacture economically the new products so greatly in demand, and we are to-day supplying apparatus for the manufacture of a large number of these products, such as aniline, acetanilide, anisidine, alpha naphthylamine, alpha-sulfonic acids, amido-naphthol, alpha-naphthol, benzoic acid, benzaldehyde, beta-naphthylamine, beta-naphthol, beta-sulfonic acids, carboic acid, dinitrobenzol, dinitro-chlorbenzol dimethylaniline, diphenylamine, Gamma acid, H acid, meta-nitraniline, meta-phenylene-diamine, meta-tolulene-diamine, metanilic acid, naphthionic acid, ortho-anisidine, ortho-phenetidine, para-anisidine, para-phenetidine, para-nitraniline, para-phenylene-diamine, para-aminophenol, phenetidine, picric acid, sulphur black, sulfonic acid, Toluidine, xylydine, trinitrotoluol (TNT), nitric acid, caustic soda, etc.

One of the first products we were called upon to produce machinery for was synthetic phenol. The methods generally used in treating sodium benzol sulphionate before fusion with the caustic soda was to take the liquor from the filter presses, evaporate it as far as possible in open pans containing heating coils and then dry the salt before fusion, either by means of heated air or by some other crude method. Seeing the field for improvement here, our laboratory started work on this problem, and it may be interesting to you to know the evolution which finally led up to the present method of operation.

We, of course, easily determined that a vacuum evaporator should be installed for reducing the liquor to a certain density, thus doing away with the open pans. The problem that presented itself, was how best to handle the evaporated liquor. Our engineers and chemists assumed that the vacuum drum dryer would be the ideal machine for treating the liquor as it came from the evaporator, but we found by actual experiment that owing to the peculiar nature of the liquor it was very difficult to secure under a vacuum a good coating on the drying drum.

We next tried the vacuum rotary dryer, but found that this machine formed the product into large cakes or balls. It was impossible to extract the moisture from the interior of these masses without spending considerable time in drying, our object here being, as in all cases, to produce the most economical method for handling a given product. We found that the experience we were having with this product coincided with that which we had had on some other products, which we worked out by using an atmospheric drum dryer for reducing the moisture content to, say, approximately 12 per cent, and then finishing the process in a vacuum rotary dryer. We found that this experiment produced

the desired results and furnished a beautiful sodium benzol sulphonate salt ready for fusing with the caustic soda. Later experiment showed that it was not necessary to reduce the moisture content in the sodium benzol sulphonate to below 12 per cent before fusing with the caustic soda, with the result that the vacuum rotary dryer has been eliminated and the atmospheric drum dryer is used exclusively for handling the liquor as it comes from the evaporator.

We later found that the "Bufokast" atmospheric drum dryer has many uses in chemical plants. The patented successful principles of operation in this dryer are the causes for its exceptional success in this field. It embodies the principles of the "Bufovak" vacuum drum dryer. The same patented automatic device for applying the liquid to the drum produces a uniform coating on the drum, and consequently a uniformly dry product. It is an ideal machine for drying materials that can be dried rapidly and without injury under atmospheric conditions, such as salts of sulfonic acid, sodium naphthalene sulphonate, and other similar products. The machine is continuous in its operation, is a great labor saver, and the finished product produced is uniform, and when desired for fusion is in excellent condition to go direct from the dryer to the fusion operation.

One of the early demands since the European war has been for a reducer for the manufacture of aniline oil. The improvements here which have been made, are the improved sludge unloading device which automatically raises the valve when open, and wedges it in position when closed, the introduction of reversible liner plates, hollow shaft and rake for the introduction of steam when desired, and the jacketed bottom for special cases.

Another development we have made is apparatus for the distilling of beta-naphthol. This consists of a still body, constructed of a special metal, and fitted with a cover in the usual way. The new features of this still is the condensing and receiving system, the condensation being drawn into an air-cooled condenser consisting of a single pipe. This pipe leads into steam jacketed, three-way valve, one of the valve openings attached to the condensing pipe, and each of the other two leads to a receiver. The steam in the jacket prevents the material from solidifying in the shelf, the material on entering the receiver passing between two glasses. By this means the operator can easily determine when it is shut off, and change from one receiver to another.

These receivers are rectangular cast-iron boxes with a door opening the full size at one side. Inside of the receiver is placed a steel box with tapered sides which fits as neatly as possible the full size of the receiver. The beta-naphthol solidifies in this box, which is easily removed and is dumped by taking out the tapered box. In addition to the foregoing, the still is supplied with a large tank in which are placed baffles to collect any

material that may pass a receiver. Beyond this tank two smaller receivers are supplied, one for containing the liquid to neutralize the vapors if any should pass this distance from the still. The other receiver is for this liquor in the event that the air current is reversed in the pipe. This allows the liquor to flow from one tank to the other as the case may be. The entire apparatus is evacuated by means of a dry vacuum pump, and the still is heated by a direct fire.

Another of our developments in the manufacture of sulfanilic and naphthionic acid and for reclaiming high-boiling-point solvents from waste is a direct-heated shelf retort, consisting of a chamber, provided with ducts passing from one side through an opening on the opposite side. Between the ducts, and inside of the apparatus, are formed shelves. The one side of this retort is provided with a door opening the full size of same. The retort can be operated either with or without a vacuum. The retort when operated under vacuum is connected with a dry vacuum pump and a condensing system between the pump and retort. The material is placed on the shelves in pans and the hot gases from the furnace in which the chamber is placed passed through the inside of the shelves. The regulation of the temperature on each shelf is made by dampers, which permit more or less of the hot air to pass through the shelf. This type of retort is far more efficient and has a much larger capacity than the previously odd-shaped affairs used for this purpose, and is much more rapid in its operation.

Another improvement that we have made is in the construction of autoclaves for the production of dimethylaniline. It has always been the practice to use an enamel or silicon lining in the autoclave, which has caused more or less trouble due to the checking and cracking and final deterioration of the enamel. This led us to develop an autoclave which uses as a liner a highly acid-resistant cast iron. The difficulty encountered in this construction was that the acid-resisting metal is more or less brittle and would not stand for the high pressure the autoclave works under in the manufacture of dimethylaniline. This led to our adopting the method of backing up the acid-resisting castings with a lead lining.

The rapid expansion of the chemical industry has brought up seriously the question of economical acid recovery plants. In this line one of the ingenious and unique developments has been the patented denitrating apparatus, which has for its purpose the distillation of nitric acid from a mixture of nitric, sulphuric and water. This particular form of construction of the machine enables this nitric to be distilled off at a high strength and reasonably free from lower oxides of nitrogen.

FIG. 2—BETA NAPHTHOL STILL

FIG. 3—DIRECT-HEAT SHELF RETORT

FIG. 4—DENITRATING APPARATUS

The reasons why results can be obtained from this apparatus and not from an ordinary plain still are as follows:

The new type of denitrating apparatus presents a very large heating surface in contact with the acid mixture to be treated. The temperature of that part of the apparatus above the level of the acid mixture cannot by any possibility rise above the temperature of the nitric acid vapors produced in the apparatus. By this means the strongest nitric acid vapors are not decomposed by coming in contact with superheated metal surfaces. Therefore, the very strongest acid, and fairly free from lower oxides of nitrogen, will result.

The distillation of the nitric acid is effected at a much lower temperature than is ordinarily possible. This is done by the injection of air at the bottom of the machine, which keeps the acid mixtures in violent agitation, and the nitric acid held in the mixture is removed most effectively by the sweeping effect of the air. The direct heat from the furnace is drawn through the double U pipe in the apparatus, which are always covered with acid. By this means the greater part of the heat is directly absorbed and the balance of the heat contained in the flue gases after leaving the double U pipes is drawn around, thus giving additional heating surface and giving the greatest degree of efficiency in operation. The distillation of the nitric acid is therefore effected under almost ideal conditions, and by the use of the air the factor of mass action (which has to be considered in an ordinary still when nearly all the acid is distilled off) does not occur in the new type of apparatus. By this I mean that when the ratio of sulphuric acid to nitric acid toward the end of a distillation becomes so great that a very high temperature has to be carried in the still, the nitric evolved must necessarily be weak.

For example, in handling a guncotton displacement system the first run-off of spent acid is, of course, reinforced with nitric and oleum, but the second displacement, which consists of approximately 18 per cent nitric, 60 per cent sulphuric and 22 per cent water, if placed in the ordinary still will only give a nitric acid on distillation of about 78 per cent to 80 per cent HNO_3 , and even at that the temperature has to be carried to about 180 to 190 deg. C., and in a fraction of the time taken by the ordinary methods.

It is well known that from guncotton-spent acid, and particularly where oleum is used in making acid mixtures, enormous quantities of sediment will fall down to the bottom of an ordinary still, which is difficult to handle, as it tends to choke the whole system. Now, in the new form of denitrating machine, after six months' work, there is not the slightest indication of sediment forming in the machine, and this can be readily understood, as the acid is kept in violent agitation during the whole time of distillation, which prevents the set-

ting of the mud always occurring in the ordinary still.

As to the kind of acid mixture best suited for this new type of machine, I would state that any acid mixture containing a nitric content above 2 per cent can be readily handled, and the nitrous contained in the acid mixture is to some extent oxidized by the large volume of air passing into the machine.

As air is used in this machine, which, of course, means that it is saturated with nitric acid to an extent determined by the temperature at which the air vapors pass through the condensers, some form of tower is absolutely essential in order to deprive the air of the nitric acid. The best form of tower for this purpose is a small one through which a very small quantity of water is allowed to trickle so that a fairly strong acid can be obtained at the foot of the tower, and no nitric acid allowed to escape at the top. An ordinary form of absorption tower can be used for this purpose and need only be quite small, 5 ft. high by 18 in. in diameter is quite sufficient.

As to the commercial value of this apparatus, as it refers to the handling of waste acid, one may sum this up in the following statements:

A stronger and higher grade of nitric acid can be obtained by the new machine than by any of the older processes.

The fuel efficiency per unit of nitric obtained is exceedingly high.

The capacity of the new machine per unit weight of acid handled is very much higher than with the old type of still.

The space occupied by the new apparatus is only one-sixth that required by the older type of still.

The life of the new type of apparatus is infinitely greater than the old type of still, as with the new form of apparatus only strong acids come in contact with the metal, and that at lower temperatures.

Some improvement has also been made in evaporators for the chemical and other fields which has been of great advantage in the development of chemical plants, which started with a small capacity and later desired to increase their production.

The "Buflovak" evaporator has the advantage that it can be doubled in capacity by merely inserting an additional belt and new tubes. This takes up very little additional floor space and gives 100 per cent more capacity.

Another development, which has met with considerable favor in chemical plants, has been the adaptation of the "Buflokast" crystallizing pan to many uses in the drying and crystallizing of products which tend to be sticky or gummy in the drying process. This crystallizing pan has been very efficient for concentrating and crystallizing material, permitting high temperatures. It has been used heretofore almost exclusively in this country for evaporating and neutralizing liquor of ammonia and nitric acid, and drying and crystallizing the finished product. This pan has also been equipped to operate under vacuum, which provides a means for the drying of sticky materials at low temperatures.

A recent development in equipment for handling acids is the so-called acid-proof or acid-resisting castings, which were first made in England and later in the United States. In the United States we have kept pace with this movement and have manufactured not only small pipes as a substitute for stoneware for conducting acids, but have made various shapes and sizes of re-torts. It is only recently that medium sized castings have been made with this metal. On account of the brittleness of the metal the problem from a foundry standpoint is a very difficult one, but advancement has been made, both in the size of the castings and in the shapes of them for acid work. No doubt the next two

or three years will see a considerably greater improvement in the quality and size of this equipment. I believe that as large and difficult castings are now being made in this country, if not more difficult ones, than in Europe. The use of castings made of this metal is bound to greatly increase on account of such castings being superior to enameled equipment and stoneware for many classes of work.

The Buffalo Foundry & Machine Company has for some years had a chemical laboratory and a physical laboratory for work required in the carrying on of its business. We are now erecting a large laboratory building, and will add very materially to the equipment already in use, not only in order to conduct many tests in our experimental dryers and evaporators, but also for research work in organic chemical lines. We expect that there will be a demand for new apparatus to handle the enlarging field of chemical products, and we hope to be able to serve in this development by having a properly equipped laboratory and competent engineering talent to carry on some of the research work.

However, as the old proverb says, "necessity is the mother of invention," it is important, first, to know what is required before apparatus can be designed for meeting new requirements. In the manufacture of chemicals, it is the man in charge of the plant who meets these new problems and who can call upon the research and designing engineer for his services in solving. It is, therefore, important that the chemists in charge of the manufacture of chemical products co-operate with the machinery manufacturers in speeding the advance in the design of machines to meet new conditions. It is true that great secrecy surrounds many of the chemical manufacturing processes in this country, and where publicity would effect the earnings of chemical companies it is wise to avoid undue publicity. But giving due regard to the protecting measures required, I believe it is nevertheless possible for manufacturing chemists to submit many problems to the manufacturers of chemical equipment, which the latter can solve to the benefit of both sides of the industry.

Buffalo, N. Y.

The Youngstown Chemists' Club has been recently organized, and the following officers were elected: President, Mr. Edwin G. Pierce, Consulting Chemist; secretary, Mr. Carl Weesner, Carnegie Steel Co.; treasurer, Mr. H. E. Moyer, Brier Hill Steel Co.

The first regular meeting Dec. 14, was a symposium on the local water situation. The Club is considering plans for a home of its own.

The Schaffer Engineering & Equipment Company, Tiffin, Ohio, has finished an installation of a No. 20 Poidometer with Liquid Measure attachment in one of the plants of the LaCled-Chrissy Clay Products Company, St. Louis, Mo., and has an order for four more from the same company.

The present installation is handling a mixture of ground fire clay in a predetermined amount, delivering same by actual weight and adding thereto, the right proportion of water, all of this being accomplished automatically and with a decrease in labor cost at this particular station.

Increasing Use of Coke as Boiler Fuel in England.—The London County Council has ordered 8 coke-burning mechanical stokers for the Greenwich power station. These will have a capacity of 100 tons of coke in 24 hours. The economic reasons for burning coke instead of coal and thus saving the valuable by-products incident to coke manufacture, are being increasingly appreciated in England.

A New Electric Zinc Smelting Process

Dr. Charles H. Fulton, of the Case School of Applied Science, Cleveland, Ohio, has been known for some time to work on the development of a new electric-furnace process for zinc smelting, for which various advantages have been claimed. The first authoritative information on this process has now come out through the granting of U. S. patent 1,213,180 (January 23, 1917), to Charles H. Fulton (assigned to David B. Jones, of Chicago).

A resistance furnace is used and the charge itself is the resistor, but the novel feature of the Fulton process is that the charge is made up into briquets which preserve their form and volume during distillation. In the closed retort chamber the briquets are placed so as to form a continuous resistor between the electrodes; the heat is developed uniformly within the resistor without local overheating.

The briquets are made up of 50 to 60 per cent by weight of ground and calcined ore, 30 to 40 per cent of pulverized coke, and 10 to 20 per cent of finely ground hard coal-tar pitch. After a uniform mixture of the three constituents has been obtained, the mixture is heated to the melting point of the pitch, which melts and softens in place and thoroughly coats each article of ore and coke. The mixture is then formed into briquets of cylindrical shape in suitable molds, in which they are subjected to a high pressure, upward of 500 pounds to the square inch, to solidify the mixture.

The briquets are next preheated for the purpose of driving off the volatile hydrocarbons of the binder (which would dilute the zinc vapor in the subsequent distillation and interfere with condensation). For this purpose the briquets are subjected to a gradually rising temperature reaching from 400 to 600 deg. C. in a reducing atmosphere (by embedding the briquets in finely crushed coke). It is even advantageous to raise the temperature to 650 or 700 deg. C. in order to convert the briquets into better conductors of the electric current. The structure of the briquets produced in this manner is that of a large number of ore particles embedded in a coke matrix, this matrix being made up of the original coke and the coke left by the distillation of the pitch binder. Such briquets have a specific resistance of 0.03 ohm per cubic inch.

Fig. 1 is a view of the furnace, with the lifting means by which the briquets are lifted into the distillation chamber or retort shown in its lower position, as it would appear either immediately after the distilled briquets have been withdrawn from such chamber or immediately before the undistilled briquets have been raised into it; Fig. 2 is a corresponding view, showing the briquets lifted into position in the distilling chamber. A is the distilling chamber with the vertical columns of briquets 23 and the electrodes 25 and 25' at their lower and upper ends. B is the condenser.

Figs. 3 and 4 are horizontal cross-sections through the distilling chamber at the points of the lower and upper ends of the briquet columns respectively. In the illustrations there are shown twelve vertical columns of cylindrical briquets 23, constituting a "charge" for the retort A, and as the furnace is designed for use with a three-phase alternating current connection of the Y-type (star type) the columns of briquets are arranged in six pairs. The columns of briquets rest upon the graphite electrodes 25 and 25', which in turn rest upon the tile-block or grid 24 which constitutes the closure for the upper end of the condenser B. The three electrodes 25' (Fig. 3) each support two columns of briquets and are located at equidistant points around

FIGS. 1 AND 2—VERTICAL CROSS-SECTIONS THROUGH DISTILLING CHAMBER A AND CONDENSER B

the block 24 adjacent the periphery of its upwardly projecting circular central portion, while the electrode 25 is a three-armed neutral point electrode, two columns of briquets being supported upon each of its three radial arms, as shown. Current is conveyed to the electrodes 25^a by three graphite electrodes 26.

At the tops of the columns of briquets the adjacent pairs of columns are connected in the manner shown in Fig. 4 by the electrodes 25', each of which is suitably shaped to rest upon and electrically connect the tops of two adjacent pairs of columns.

If we take, for the purposes of explanation, the current conveyed to the left-hand pair of columns of briquets in Fig. 3 by the left-hand electrode 26 there shown, the current will pass upward through said columns of briquets to the electrode 25' which rests upon their upper ends (Fig. 4), thence through said electrode to the upper end of the adjacent pair of columns of briquets, thence downwardly through said columns to the radial arm of the electrode 25 upon which said columns rest, being the upper left-hand arm of said electrode in Fig. 3, thence to the neutral point at the center of said electrode. The passage of the current for the other pairs of columns of briquets is similarly all convergent on the neutral point of the electrode 25, which gives the common Y-connection of the alternating three-phase current.

The current is supplied to the distilling chamber from an adjustable-voltage transformer. The amount of current passed through the briquets is preferably at first relatively small, so that the walls 1 of the retort A will be heated rather gradually to about 700 deg. C. or 800 deg. C. by radiation from the briquets. The cur-

FIGS. 3 AND 4—HORIZONTAL CROSS-SECTION THROUGH DISTILLING CHAMBER AT BOTTOM AND TOP OF BRIQUET COLUMNS RESPECTIVELY

rent may then be rapidly increased and the briquets raised to a distilling temperature. The zinc vapor then freely evolved will fill the retort space and pass down between the electrodes 25 and 25^a and through the openings 20 in the block or grid 24 into the condenser B. By means of carbon resistors in the shell the condenser is kept at a temperature between 500 deg. and 650 deg. C., the higher temperature obtaining near the top and the lower near the bottom. The zinc vapor strikes against the condensing plates 19, and circulates between the same and the walls 18, as well as through the openings 21 and in the annular space 22 surrounding the walls 18. The large surfaces afforded by these parts and the interior walls 2 of the condenser serve to rapidly condense the zinc vapor into liquid zinc, which collects in the bottom of the condenser. The carbon monoxide gas evolved in the distillation of the briquets passes out and burns at the opening 32 in the bottom of the condenser. The liquid zinc is tapped off at the tap 31. When the briquets are completely distilled, which is indicated by the dying down of the flame at the opening 32, the condenser is lowered by means of the hydraulic apparatus into the position shown in Fig. 1, and the briquets then quenched rapidly with a spray of water and removed from the grid 24, a fresh charge put in their place, and the condenser again raised into distilling position and the described operation then repeated.

Ceramic Engineering.—The Department of Ceramic Engineering of the University of Illinois, Urbana, Ill., will issue shortly a new bulletin describing in detail the courses, both graduate and undergraduate, which it offers in ceramic engineering and ceramic chemistry. The bulletin will also contain an illustrated description of the new laboratory and its equipment, and a list of the names and addresses of the graduates of the department since its establishment.

A Method of Determining the Density of Flue Gases*

By James Alex. Smith

Engineers, whether power, metallurgical or manufacturing, can always ascertain the density of the gases within their province, either by chemical analysis or precision weighing. But it is not always essential to know the chemical composition; or the composition may be deducible with sufficient accuracy if the density is known. Then methods of a simpler or more direct character have a use, particularly when it is desired to study cause and effect concurrently, and without any appreciable intervening interval during which the cause might vary.

The purpose of this paper is to describe a mode of determining gas density by gage reading. So far as the writer is aware, the method is new.

General Principles.—The basic theorem is that the densities of gases and their pressures per unit area of base are directly proportional when the gas columns are of equal height. Hence, if a column of air in a vertical tube of known height is displaced by a given gas, the barometric and thermometric conditions remaining constant, the densities are in the simple ratio

$$D = \frac{P \pm P'}{P} \quad (1)$$

when

D = Density of the given gas referred to air taken as unity,

P = Known air pressure due to column height, and
P' = Difference ($\pm$) of pressure due to gaseous displacement.

Pressure Measurement.—Assume that an accuracy within 1 per cent of the total air pressure due to the vertical or column height is required; in other words, that a pressure due to the air in a column the one-hundredth of the height of the column in the given case must be evaluated. This order of minuteness of magnitude at once contraindicates mechanism subject to friction, and indicates the use of "frictionless" liquid gauges.

Postulating that, without the introduction of undesirable complications, 0.02 in. is the smallest significant difference of level of such a gage, then the relation of that minimum gage space to the minimum correlated gas-tube height (h) is given by the equation

$$h = .02 \text{ in.} \times 100 x \quad (2)$$

when x is the specific gravity of the gage-liquid referred to air as unity. Therefore water, which is about 772 times heavier than air, if used in a simple siphon gage, and under the conditions postulated, requires a complementary gas-tube not less than $0.02 \text{ in.} \times 100 \times 772 = 1,544 \text{ in.} = \text{about } 130 \text{ ft. in height.}$ Conversely, if the height (h) in inches be given, then the maximum specific gravity of the possible gage-liquid (air, as before, being taken as unity) is determined by the formula

$$x = \frac{h}{2} \quad (3)$$

Any convenient value may be assigned to h . Let, then, the vertical height of the gas column be 100 in. Then x = specific gravity 50. That is, for such a tube height, a liquid is indicated not more than 50 times

heavier than air, or, $\frac{772}{50}$ 15.44 times lighter than water.

No such light liquid is known; but its equivalent may be attained if two immiscible liquids are caused to partially equilibrate each other in such a manner that the difference (which may be made as small as desired) of the specific gravities becomes the measure of the equivalent specific gravity of the liquid system as a whole.

A gage on the differential principle, capable of readily dealing with gas pressures of the small magnitude in question, has already been described by the author in the "Proceedings" for November, 1909, vol. x, page 155, under the title, "A Simple, Sensitive, Two-Liquid Differential Gage for Measuring Small Pressures."

Gas Tube.—The gas tube is very simple. In the example illustrated it consists of a piece of $\frac{1}{8}$ -in. wrought-iron gas-barrel, A, 100 in. in height. At the bottom two stopcocks, B, C, permit alternative connection to a gas-source or to a gage, E. To check diffusion the passage through the latter cock should be reduced to a pin-hole. At the top a third cock, D, opening into the air, permits the tube to be gas-flushed and filled, and when the main passage is closed continues the connection by a minute by-pass large enough to preclude any possible barometric difference of pressure between the gas inside and the air outside the tube, yet so small that diffusion is negligibly slow. The surface of the liquid in the gage cistern and the bottom of the gas tube must be approximately at the same level.

Calibration.—If the gage constants are unknown, a simple, comprehensive calibration covering all the factors can be effected thus: All parts being filled with air, adjust the gage to zero. Then displace the air in the tube with any easily generated or procured gas of known density, for instance CO_2 , the specific gravity of which is 1.524. Then the pressure upon unit of base of 100 in. vertical of CO_2 is equal to the pressure of $100 \times 1.524 = 152.4 \text{ in. of air.}$ Therefore, the consequent liquid displacement due to the displacement of the air by gas is equivalent to that which would be caused by an air pressure of $152.4 - 100.0 = 52.4 \text{ in.}$ The scale can be graduated or interpreted accordingly.

Corrections.—When relativity only is required, corrections may be dispensed with. The case of the im-

A—Gas tube. B—Inlet gas cock. C—Gage cock. D—Outlet gas cock. E—Differential gage.

NOTE.—The barometric equalizing vent (at D) is not shown. It consists of a piece of clockmaker's "bushing wire," 1 in. long and $\frac{1}{80}$ -in. bore.

* A paper read before the Victorian Institute of Engineers and published in *London Engineering*.

mediate effect of draught volume variation upon chimney-gas density is an example.

But if absolute readings are required, and if the barometric and thermometric conditions differ from those which may have been assigned in respect to P (formula 1), and upon which the value of the gage divisions is computed, then a corrected value P'' must be substituted for observed P' in formula (1); then

$$P'' = \frac{(461 + t) 29.92 \times P'}{461 \times b} = \frac{(461 + t) \times P'}{15.41 \times b} \quad (4)$$

when

t = Observed temperature on Fahrenheit scale,

b = Observed barometric pressure in inches,

P' = Observed pressure due to gas displacement, and

P'' = Corrected value of observed displacement pressure.

Strictly, a further correction should be made to compensate for the variation in the gas system volume, due to the movement of the liquid in the gage. Usually, however, this amount is so small that it may be neglected in practice.

Scales.—The actual graduations may be in any convenient terms, i.e., density or specific gravity, percentages, or direct evaluations of the major object of the test.

Variants.—(i) The mode is equally applicable in the case of density change due to chemical reaction other than combustion.

(ii) In the case of inconveniently high tubes, all adjustments may be brought within operative reach by constructing the tubes as an inverted $\cap$ providing that the minute equalizing vent must then be placed at the vertex, and must remain permanently open.

(iii) A gas tube within a chimney and extending to its full height affords a means of ascertaining the density of the chimney gases at the mean temperature within the whole stack. From this may be deduced the potential ascensional power of the gases, a result not given by the ordinary draught gages, which show the utilized value only.

(iv) Obviously portability can be attained by constructing the tube in screwed sections.

(v) Photographic continuous records can be attained by the use of any of the well-known devices. This implies a constant passage of gas, therefore precautions must be taken against the vitiation of the results by the introduction of extraneous pressure head, either by periodically cutting off the gas supply, or by making the inlet very small in comparison with a relatively large outlet permanently open. Necessarily there will be a lag in the records in respect to time.

Synopsis of Recent Metallurgical and Chemical Literature

Rubber

Vulcanization of Rubber.—The researches of the eminent Russian chemist I. I. OSTROMYLSKI, originally published in the *Journal of the Russian Physico-Chemical Society*, were translated for the *India Rubber Journal* (England) and published in its Sept. 30, 1916, issue. They have been republished in the *India Rubber World* for Nov. 1, 1916. The papers describe a most interesting set of researches on the vulcanization of rubber without the use of compounds containing sulphur. Up until the present investigations were made no method of vulcanizing caoutchouc was known in which a sulphur free organic or mineral compound was used. The chemical and physical theories of vulcanization suggested a whole series of such compounds, and Mr. Ostromylski has succeeded in discovering by

the application of physical chemistry two new methods for hot vulcanization. From a consideration of the properties of sulphur in oxidizing ethylenes, melting point, vapor pressure at the temperature of vulcanization, and other properties, substances were found having similar properties which would effect the vulcanization of rubber. Among these is 1:3:5 trinitrobenzene, and also other nitro-compounds, perbenzoic acid, gaseous oxygen, and various peroxides, per acids, etc. The work of Ostromylski is a most interesting and valuable contribution to the chemical industry, and a study of the chemical principles involved is very interesting. His work leads to a more rational explanation of the mechanism of vulcanization.

Natural Gas

Conservation of Natural Gas in Oil Fields.—A description of a process for the prevention of natural gas waste in oil fields is given in Bulletin 134, recently issued by the Bureau of Mines. The authors are JAMES O. LEWIS and WILLIAM F. McMURRAY.

"One of the most shameful wastes of this country's natural resources has been that of natural gas in the oil fields," the authors state. "This waste has been occasioned very largely by not having efficient and cheap methods of controlling the gas, nor adequate laws and regulations to enforce the control.

"Soon after the establishment of the Bureau of Mines investigations were started with the view of finding means of lessening this waste. In 1913 engineers of the Bureau of Mines were sent to Oklahoma to investigate the waste and to recommend methods for its prevention. These engineers recommend the mud-laden fluid system, which had been previously used in Texas and California, and demonstrated that the method was equally applicable to the conservation of gas in the Mid-Continent and Eastern fields."

Bulletin 134 consists of three parts. The first part covers the theory of the process and the manner in which it is used, so that the operator will understand the principles and be able to use the process even though he has had no previous experience with it. There are numerous figures illustrating apparatus and showing conditions under which the process has been used. The bulletin shows how mud-laden fluid may be used advantageously to conserve the oil and gas, shut off water, overcome high gas pressures, prevent fires and accidents, drill through loose and caving formations, save casing, and to protect casing against corrosive waters. It tells how many sources of trouble, danger and expense may be eliminated. The latest apparatus and methods, including the circulator method of drilling with cable tools, are given.

In the second part are accounts of many demonstrations of difficult cases in the Mid-Continent field. In many instances these demonstrations were made after all other methods had failed. Demonstrations were made in overcoming high pressures, in saving casing, in protecting formations, and in overcoming other difficulties. The method has now been used in several hundred cases in the Mid-Continent field. It has been the means of conserving an enormous quantity of gas, and has made possible the practical enforcement of conservation by the State and Federal authorities in Oklahoma.

In the third part are given copies of the oil and gas conservation laws of Oklahoma, and the regulations governing oil and gas operations on restricted Indian lands, which are under the supervision of the Federal government. The main purpose of this paper is to demonstrate practical means for conserving oil and gas, and these laws and regulations are included to show what technical principles should be embodied in laws and regulations to enforce conservation.

Copper

Metallurgical Operations at the Chile Exploration Co.—C. A. Rose, in the August, 1916, number of the *Teniente Topics*, pages 19 to 23, gives a very interesting description of the metallurgical work done at Chuquicamata, Chile, by the above-named company. The process used was worked out at Perth Amboy on a 15-ton plant basis by E. A. Cappelen Smith, and it is claimed by the author that the process as now used on a 10,000-ton scale works as satisfactorily as on the small scale. The commercial copper ores treated are chalcocite, covellite, brochantite, chalcantite, kroenkite, atacamite, chalcopyrite, bornite and enargite.

The plant as it is now operated may be divided into the following units: crushing plant, leaching plant, dechloridizing plant, pumphouse, electrolytic tank house, smelting and melting plant. The crushing plant consists of two No. 10 McCully gyratory crushers, two 48-in. Symons disc crushers and eight 54 x 20-in. high-speed rolls. Construction is now under way for the installation of two 84 x 60-in. Superior jaw crushers to relieve the overburden which was, up to date, thrown on the original crushing plant. Additional grizzlies and screening appliances are also being installed in order to by-pass the fine material around each crusher and to return to the rolls the oversize from the final product delivered to the leaching plant. It is expected that with these improvements the full tonnage of 10,000 tons of $\frac{1}{2}$ -in. material will be supplied to the leaching department.

In the leaching plant are six leaching tanks, each 150 ft. long, 110 ft. wide and 16 ft. high, and nine solution tanks set on a somewhat higher level. All tanks are set end to end and are built of reinforced concrete lined with 1 to $1\frac{1}{4}$ in. of mastic asphalt. The mastic consists of one part of Trinidad asphalt and four parts of sand. After melting the asphalt, it is mixed with the sand in a Gulich asphalt mixer, and after thorough incorporation is poured, while still hot, between steel forms and the sides of the tanks. The steel forms are built in sections as the lining of the tanks is cast. On the sides of the vats the mastic is kept in place by means of expanded metal laths embedded in the mastic and anchored to the sides of the tanks.

The false bottoms of the leaching tanks are constructed of 6 x 6-in. timbers, laid 10 in. apart on the floor of the tank. Above these and laid crosswise are placed planks 2 x 6 in. and 3 in. apart. This structure is then covered with cocoa matting, which in turn is covered by 2 x 6-in. planks, $\frac{1}{2}$ in. apart. On starting operations a 1-ft. layer of coarse material is spread over the false bottom. On discharging the tank this bottom layer is left intact and forms a very satisfactory sand filter. Eight 6-in. outlet pipes are distributed evenly around the bottom of each tank. These pipes unite in a 15-in. main leading to the pumphouse. The pipes conducting acid solutions are lead-lined iron pipes, joined with standard flanges and rubber gaskets, which take up the expansion and contraction due to any temperature changes in the weather conditions.

In the process of leaching, a portion of the last solution drawn from the tanks is removed for complete deposition of the copper. This amount is so calculated as to compensate for the increase in total volume of the solution, due to the addition of more water as a last wash on the ore than is discharged as moisture in the residue, and also removes from the system continually the impurities that are introduced by the ore and accumulate in the solution. After freeing this portion of the solution from copper, it is

discarded. The essential impurities are the sulphates of sodium, potassium and magnesium. When these have accumulated to the extent of 150 grams of sodium sulphate, 10 grams of potassium sulphate and 65 grams of magnesium sulphate per liter, the discarded solution in each cycle removes the same quantity of these salts as is introduced into the system by the quantity of ore leached. Iron sulphate does not seem to accumulate to any great extent in the process. Any possible chlorine, which might enter the solution, is previously taken care of in the dechloridizing plant.

After filling a tank with ore, the first solution is introduced by upward percolation, preventing thus the fine particles of ore to drop on the bottom, which would be the case if the solution were applied from the top. After allowing this solution to remain in contact with the ore for 36 to 48 hours, it is drawn off and replaced by downward percolating new solution.

The solution withdrawn for the precipitation of the copper contains about 6 per cent of the total copper content, extracted from the ore. The copper thus obtained is either cast into soluble anodes and used in the electrolytic tanks for making starting sheets or is delivered to the dechloridizing drums for the precipitation of cuprous chloride. The acid lost in the discarded liquor and also in the removal of the acid element chlorine in the dechloridizing plant is nearly equivalent to that gained from the copper sulphates chalcantite and brochantite, provided the ore has a copper content not less than 2 per cent and does not exceed 0.2 per cent chlorine. However, an acid plant is in connection with the works, so as to supply any excess acid if needed. This is simply a precaution and not a necessity at present.

The dechloridizing plant comprises 22 tube-mills 30 ft. long with an internal diameter of 4 ft. They are built of $\frac{1}{2}$ -in. steel shells lined with thin lead and with an inside shell of earthenware set in asphalt mastic. They are filled nearly half full with granulated copper and revolve at 8 r.p.m. Gravity flow conducts the solution from the solution tanks to the dechloridizing plant, where it is divided to supply the 22 tube-mills. The chlorine on its passage through the mills forms cuprous chlorid, which remains in the solution finely divided and is carried on by the stream of solution into seven Dorr thickeners. The pulp is dewatered in these thickeners, so that only 50 per cent moisture remains in the product. This product is then delivered to an Oliver filter and the cake thus obtained is sent to the smelter, where it is mixed with limestone and coke and smelted in a blast furnace. The furnace products obtained are black copper and calcium-chloride slag.

Various treatments of cuprous chloride have been tried, such as smelting, electrolysis and cementation, and it has been decided that the cementation was most beneficial under the circumstances of the operation of the plant. This decision is due to the amount of cement copper required in the dechloridizing mills. The cuprous chloride will be dissolved in brine solution and the copper precipitated on scrap iron. The amount of iron used will be approximately half of that used in the ordinary cement copper processes, due to the fact that the copper is present in the cuprous and not in the cupric form. Part of the ferrous chloride formed in the process will be used for dissolving more cuprous chloride instead of using salt.

The clear solution from the thickening tanks is pumped to a large, asphalt-lined concrete storage tank of 1815 cu.m. capacity. From here the solution is conducted to the electrolytic tank house by means of

gravity. The novel features of this part of the process consist in the use of magnetite anodes, asphalt-lined cement electrolytic tanks and launders, the use of large-sized cathodes (3 ft. x 4 ft.) and the cascading of 16 tanks in one solution circuit. Since the outbreak of the war in Europe the magnetite electrodes have been replaced by such made of duriron, as it was impossible to produce the fused magnetite electrodes locally or in the United States, Germany being the only place where electrodes of this type could be purchased. Duriron electrodes answer the purpose fairly well, resisting the dissolving action satisfactorily, but not as well as the fused magnetite. They surpass the magnetite electrodes in strength, but have a much higher over-voltage, which is a decided disadvantage. Duriron electrodes require about 15 per cent more energy than do magnetite electrodes for the deposition of the same amount of copper. This excess energy goes into heat, and at times this heat becomes so high as to soften the mastic lining of the tanks.

The purity of the copper produced is approximately 100.5 to 101 per cent Matthiessen's Standard, being somewhat higher than that produced in American electrolytic refining practice.

Gallium

Electrolysis of Gallium Solutions.—A contribution from the Physical and Chemical Laboratories of Yale University on the production of gallium "trees" is given by HORACE S. UHLER and PHILIP E. BROWNING in the American Journal of Science for November, 1916.

During the process of separating metallic gallium from an alkaline solution by electrolysis it was noticed that black coral-like deposits sometimes formed around the cathode instead of the bright liquid globules which were expected.

The electrolyte used was obtained in the following manner: Lead residues were shaved into small pieces with an ordinary iron ice-plane and dissolved in a solution made from equal volumes of water and strong nitric acid. On cooling, most of the lead crystallized out as the nitrate. Concentrated sulphuric acid was then added to the filtrate and the resulting liquid was evaporated nearly to dryness. The insoluble lead sulphate was removed by filtration after the addition of water. Silver was next precipitated as the chloride by treating the filtrate with hydrochloric acid. By adding an excess of ammonia to the filtrate the hydroxides of gallium and indium were thrown down while most of the copper and zinc compounds were kept in solution. When working with large masses of material it was found necessary to repeat the last operation in order to effect a satisfactory purification of the hydroxides of gallium and indium. Finally, these hydroxides were separated from each other by taking advantage of the facts that indium hydroxide is insoluble in a solution of sodium hydroxide, whereas gallium hydroxide is readily soluble in an excess of caustic soda. The filtrate thus obtained constituted the electrolyte used in the cells. Each step was checked spectroscopically and found to produce satisfactory and efficient separations.

The electrolytic cells consisted of the following assemblage of very simple parts. The vessel containing the liquid was an ordinary glass crystallizing dish 10 cm. in diameter and 6.3 cm. deep. The anode was a thin rectangular sheet of platinum foil, the edges of the submerged portion being 5.5 cm. horizontally and 3.5 cm. vertically. The cathode consisted of a platinum wire sealed into a glass tube with about 2 mm. projecting at the lower end.

The current used was 0.28 ampere. The trees were

formed at about 0 deg. C. and the cell was cooled with ice. The gallium trees closely resembled certain arborescent forms of native copper.

Recent Metallurgical and Chemical Patents

Iron and Steel

Open-Hearth Steel Process.—A process for the manufacture of steel by the basic open-hearth process is patented by ALFRED E. DAVIES of Bilston, England. The process consists in coating the bottom and sides of the basic lined bath of the furnace with a special slag, after the metal of a previous charge has been tapped out. The method as used in practice is given as follows:

"Assume that there is in the furnace a molten charge of metal and slag which has been partially worked in the usual way until the bulk of the silicon and phosphorus in the metal has been removed, the slag is then tapped off by tilting the furnace and further additions of lime, iron ore and oxides are made to the furnace, in order to remove the last traces of impurities, thus forming in the second part of the process the rich slag above mentioned, which it is intended to retain in the furnace for the purpose of coating the lining. The metal is tapped off when finished without allowing the slag to run out, and the slag is further enriched and thickened by lime and metallic oxid additions and the furnace tilted repeatedly as above described in order to coat the enriched and thickened slag on the bottom and sides of the furnace lining ready for the next charge of molten pig iron, which is then poured in and a reaction commences which removes the bulk of the impurities, this bringing us to the point which the description of this process started." (1,198,827, Sept. 19, 1916.)

Process of Breaking Steel Bars.—A novel process of breaking steel bars is patented by PIERRE V. L. BEL-LANGER of Paris, France. At the point in the bar where it is to be broken the bar is heated with an oxidizing blow-pipe flame. The metal becomes brittle at that point and, the bar being placed between two supports, is broken by pressure or blow on the opposite side to which the heating has been done. A flame temperature of about 700 deg. C. is used. It is claimed that the breaking of steel bars can be easily and quickly accomplished by this method. (1,201,137, Oct. 10, 1916.)

Reversing Regenerator-Furnaces.—A flue and valve arrangement for reversing regenerator furnaces is patented by LUTHER L. KNOX, of Avalon, Pa. (assigned to the Knox Pressed and Welded Steel Company of Pittsburgh, Pa.). The claim is as follows: "In a flue and valve arrangement for regenerative furnaces, the combination of air and gas regenerators, a stack flue running transversely of the regenerators, a continuous port connecting each of the regenerators with said stack flue, said ports being at the same level as the stack flue and all opening directly into the same side of said flue, each port having an admission valve in its upper wall, and each port also having a vertically movable damper between said valve and the stack flue; substantially as described." (1,203,748, Nov. 7, 1916.)

Welding Compound.—A compound to be used for welding iron and steel is patented by CHARLES W. PHELPS of Coupeville, Wash. The compound consists of nine parts pulverized "volcanic ash" and one part common salt. The metals to be welded are heated to cherry red, coated with the compound and the metals heated to a white heat, when hammering is applied. (1,199,020, Sept. 19, 1916.)

Tool-Steel Alloys.—RICHARD H. PATCH and RAD-CLIFFE FURNISS, of the Midvale Steel Company, patent a non-deforming tool-steel particularly adapted for dies, taps, reamers, and cutting tools for lathes and planers; it contains 79 per cent steel, 19.5 per cent chromium, and 1.35 per cent carbon. (1,206,902, Dec. 5, 1916.)

A partial substitution of cobalt for tungsten with very beneficial effects in tungsten-chrome steels is the predominating feature of another patent of the same inventors. A preferred composition is chromium 4 per cent, tungsten 13.5, vanadium 1.5, cobalt 15, iron 65, carbon 0.65. (1,206,834, Dec. 5, 1916.)

A third patent of the same inventors refers to the fact that by the addition to steel containing less than 1 per cent of carbon, of certain proportions of molybdenum, chromium and cobalt, the alloy becomes easier to forge, and less subject to sudden inexplicable physical effects; it also performs much more uniformly as cutting tool than do the known molybdenum tool steels. A typical composition is 4.0 per cent chromium, 8.0 molybdenum, 1.5 vanadium, 5.0 cobalt. (1,206,833, Dec. 5, 1916.)

Preparing Iron for Castings.—A patent of WILLIAM G. KRANZ, of the National Malleable Castings Company, relates to the treatment of iron intended to be made into castings, so as to overcome the difficulties resulting from the presence of relatively high carbon, manganese and silicon. The process is well indicated by the fourth claim which reads as follows: "The process of preparing iron for castings which consists in melting iron in a melting furnace, tapping a portion of such molten iron from said furnace and substantially removing its carbon in a Bessemer converter, adding said molten decarbonized metal to a larger portion of the molten iron from said melting furnace whereby the carbon in the combined charge is reduced and equalized, but remains above 1.50 of carbon, and finally treating the combined charge in a refining furnace without further substantial reduction of carbon." (1,206,861, Dec. 5, 1916.)

Manufacture of Iron and Steel.—A process of controlling the carbon content of iron and steel is patented by BRUCE FORD of Philadelphia, Pa. The process consists in supercarburizing molten iron in a Bessemer converter by alternately passing through the iron a hydrocarbon gas and air through separate valves. This carburized iron is then added to decarburized iron in another converter and the final product is obtained. The ultimate carbon content is determined by the amount of supercarburized iron added. As this latter iron has practically always the same carbon content, no chemical analysis is stated to be necessary. (1,205,611, Nov. 21, 1916.)

Titanium

Titanic Oxide.—LOUIS E. BARTON of Niagara Falls has patented a method of obtaining titanic oxide from ilmenite ores. The patent, which is assigned to the Titanium Alloy Manufacturing Company of Niagara Falls, relates to methods described in previous patents Nos. 1,106,409 and 1,106,410, dated Aug. 11, 1914, and No. 1,171,542, dated Feb. 15, 1916, granted to Mr. Barton and AUGUSTE J. ROSSI. These previous patents refer to a process in which the ilmenite ores were melted with an alkali sulphide, followed by lixiviation with water. The mixture was then heated in a bath of dilute sulphuric or hydrochloric acid, which dissolved out everything but the titanic oxide. The objection to the process was the production of hydrogen sulphide from the acid and ferrous sulphide. The present patent proposes to avoid this by the use of chlorine in lixiviation instead of acids. (1,201,541, Oct. 17, 1916.)

Electric Furnaces

Electric-Furnace Control Apparatus.—Apparatus for controlling electric furnaces, particularly arc furnaces, by connecting the electrodes or electrodes with a mechanism actuated by an electric motor is patented by JOHN A. SEEDE of Schenectady, N. Y., assigned to the General Electric Company. The motor is controlled through relays by a circuit-closing magnet responsive to variations of power in the furnace circuit. A switch is also provided for automatically disconnecting the control apparatus, thereby stopping the motor, when the voltage of the furnace supply current falls below the value to which the apparatus is adjusted. (1,206,603, Nov. 28, 1916.)

Hydrometallurgy

Wet Ore Extraction Process.—CHARLES S. BRADLEY of New York has patented an extraction process which is described especially in connection with copper ores containing iron and aluminium which it is desired to eliminate. The finely divided ore is first heated and the dust and fumes passed into an absorber. Both the roasted ore and the products from the dust and fumes absorber are then conveyed to a solution drum where the sulphates are converted into chlorides by the action of calcium chloride solution. The solution is then filtered to remove the gangue material and treated in another drum with calcium carbonate, which precipitates the high valency copper compounds (cupric chloride) and the iron and aluminium. The solution is filtered and the filtrate containing cuprous chloride and zinc chloride is treated with calcium oxide to recover the copper and zinc. The precipitates of cupric, iron and aluminium compounds are returned to the process ahead of the solution apparatus in order to furnish enough iron to insure all of the copper being extracted from the ore, as the iron will not go into solution until all the copper is dissolved. A further object of returning the high valency compounds is that they unite readily with sulphuric and sulphurous acids and form a certain amount of cuprous copper, thus making the process a cyclic one with continual withdrawal of cuprous solution. (1,204,932, Nov. 14, 1916.)

Oxygen Manufacturing Company Expanding Its Operations

The great increase in the demand for oxygen and acetylene gases for welding and cutting is manifested in the rapid growth of the latest company in this field. The Air Reduction Company, which was organized early in 1916 for the manufacture of oxygen and nitrogen from the air by the Claude process, now has nine plants in operation and contemplates putting a new one in operation every five weeks. A short account of the company was given in our issue of June 15, 1916, page 715. The Claude process is used by the American Cyanamid Company in Canada, and was described in our Vol. XIII, pages 187 and 312 (1913).

The company had at the start a contract with L'Air Liquide Société de Paris for rights to the Claude process for the manufacture of oxygen and nitrogen from the air. Complete equipment for four plants was to have been furnished with the contract to the American company, but the French Government took three of them because of the need of their products for war purposes. As soon as this situation became known to President Birge of the Air Reduction Company, he obtained control of the Superior Oxygen Company, which was using a somewhat similar process.

The principal plants are in Brooklyn, Chicago, Phila-

delphia, Buffalo, Pittsburgh, Defiance and St. Louis. Other plants or warehouses of the company are in the Bronx, New York City, Jersey City, Passaic, Paterson, Chicago Heights, Davenport, Grand Rapids, Joliet, Milwaukee, Peoria, Fort Wayne, Louisville, Toledo, Dayton, Baltimore, Boston, Detroit and Cleveland. The largest Claude oxygen plant in America is in Philadelphia. The company has also taken over one of the largest companies engaged in the production of acetylene, so that it will be able to furnish both the oxygen and the acetylene gases, together with a full line of equipment such as cutting and welding torches. Further, the company has made plans for the production of calcium carbide on a large scale, and for the production of several distinct lines of nitrogenous products both for use as fertilizer and chemical work. One of the most recent efforts of the company has been an educational campaign for demonstrating the uses of the oxy-acetylene torch in trade schools, manual training schools and technical institutes.

The capital stock of the company has been increased from \$4,500,000 to \$12,000,000.

An Apparatus for Locating Thermal Transformation Points

The more stringent requirements of designers of automobiles, aeroplanes and other machinery have caused more attention to be given to the proper heat treatment of steel and other metals. The strength, hardness, ductility and toughness of steel depend almost as much upon the temperatures at which it is worked, hardened, annealed and tempered as upon its chemical composition. Unless the temperatures are known accurately and with certainty, these qualities cannot be depended upon.

An apparatus for locating critical, recalcence and decalcence points, embodying the approved neutral-body method has been developed by the Leeds & Northrup Company, of Philadelphia, Pa. The method consists essentially in heating a small sample of the metal in contact with a larger neutral body and simultaneously measuring the temperature of the sample by a thermocouple and the temperature difference between the sample and the neutral body by a difference thermocouple while the furnace is being slowly heated and cooled. The apparatus plots these two quantities as co-ordinates upon a rectangular chart and the temperatures at which the various transformations occur are easily indicated in an unmistakable manner by rapid increases in the temperature difference between the sample and the neutral body. For example, at the A_c point, due to the solution of carbon on heating, the temperature of the sample lags markedly behind that of the neutral body.

The thermocouple used for measuring the difference between sample temperature and neutral body temperature is composed of two pieces of platinum joined by a short piece of platinum-iridium alloy. One of the junctions of the couple is in contact with the sample and the other in contact with the neutral body. The platinum-iridium couple develops a high electromotive force, which changes with temperature at a nearly uniform rate and is therefore well adapted for the purpose.

For indicating the changes in the electromotive force due to these transient differences in temperature between sample and sample holder a sensitive reflecting galvanometer is employed.

For measuring the temperature of the sample a platinum, platinum-rhodium thermocouple is employed in connection with a potentiometer.

In order to eliminate the labor and the possibilities

FIG. 1—TRANSFORMATION POINT CURVES FOR LOW-CARBON CHROME VANADIUM STEEL, (LEFT), HIGH-CARBON NICKEL STEEL, (CENTER), AND LOW-CARBON NICKEL STEEL (RIGHT)

of error involved in reading off the temperatures and temperature difference simultaneously from two different instruments, noting down the figures and subsequently constructing a curve, a transformation point indicator, which constructs its own graphical chart has been developed.

The paper upon which the chart is to be made is mounted upon a drum, which also carries the potentiometer slide wire. Bearing upon this drum is a pen. As the drum is revolved to keep the potentiometer in balance, the pen automatically records the corresponding electromotive forces, or temperatures, upon the paper.

The pen, together with a semi-transparent target, is mounted upon a carriage and this carriage can be made to travel parallel to the axis of the drum by rotating a worm shaft. The operator making the curve moves this carriage in such a way as to keep the spotlight from the galvanometer connected to the difference couple always on the semi-transparent target. By so doing the pen is caused to move back or forth across the record whenever the difference in temperature between sample and neutral body changes.

Representative transformation point curves obtained with the apparatus are shown in Fig. 1.

Opening of Bureau of Mines Building in Washington.—Invitations were issued to 1500 mining and metallurgical men of the Northwest to attend a smoker at the Bureau of Mines Building on the campus of the University of Washington, Jan. 12. The smoker marked the formal opening of the Federal mining and metallurgical experiment station in this building. Dorsey A. Lyon, head of the station, spoke on "The Purpose of the Station," and Robert F. McElvenny, superintendent of the Tacoma smelter, spoke on "The Metallurgical Situation in the Northwest." Music, boxing, wrestling and Japanese fencing were provided for the amusement of the gathering and a most enjoyable time was had.

A Device for Automatically Testing Liquids

A device for testing liquids continuously and automatically has been developed and patented by Walter C. Raddant of Elia, Cuba. It is being used successfully in testing for sugar in boiler feed water. A sectional view of the apparatus is shown in Fig. 1. The glass tube with graduations shown at the left in the center of the two larger tubes is used as a mixing tube. The larger outlet at the top of this tube is an inlet pipe, and the smaller one a vent pipe. The container at the left is used for holding an indicator and the container at the right holds acid. The containers and the mixing tubes have spring valves, the containers emptying into the mixing tube and the mixing tube having a bottom outlet. The electrically operated device at the right, consisting of a clock and electromagnet, actuates the cords connected to the plug cocks of the containers and mixing tube.

In operation the liquid to be tested is supplied to the mixing tube. At a predetermined moment the minute hand will make contact with the first screw. This energizes the right-hand electromagnet, exerting a pull on the cable and the opening valve of the container on the

FIG. 1.—VERTICAL SECTIONAL VIEW SHOWING ARRANGEMENT OF PARTS OF LIQUID TESTING DEVICE

left. This permits some of the chemical indicator to flow from the container to the mixing chamber. After a predetermined interval of time has elapsed the hand reaches the next contact screw, where the foregoing operation is repeated and the container on the right opens. When the hand reaches the third contact screw the operation is again repeated, the bottom valve opening. It is pointed out that the valves only remain open while the minute hand is in contact with the screws, the valves immediately closing by virtue of their respective retractile springs. However, the bottom valve remains open a sufficient time to permit all of the contents of the tube to flow through the outlet and permitting some of the incoming liquid to wash the tube before the valve closes.

It would seem possible to apply the idea to any number of containers and mixing tubes, provided the action of the plug cocks could be made positive enough to give the desired proportions of reagents.

Society of Glass Technology Formed in England.—At a meeting held at Sheffield University on November 9th a society was formed to represent the glass manufacturing interests and to be known as the Society of Glass Technology. It will be a national society and will hold meetings at various places. Mr. W. F. J. Wood was elected President for the coming year, and Dr. W. E. S. Turner, of the University, Sheffield, secretary.

Personal

Mr. J. R. Baylis has been appointed bacteriologist of the Montebello filtration plant, of Baltimore. He was formerly chemist and manager of the Jackson, Miss., waterworks and filtration plant.

Mr. George M. Berry, president of the Syracuse Section of the American Chemical Society and chief chemist of the Halcomb Steel Company, Syracuse, N. Y., since its organization in 1905, has been secured by Syracuse University to give a special course of lectures on metallurgy in the College of Applied Science. These lectures will cover the metallurgy of the non-ferrous metals and that of iron and steel.

Mr. Felix Dreyfus, vice-president of Herman & Herman, Inc., manufacturers and dealers in coal tar products and intermediates, sailed for Genoa on Jan. 23, to visit the company's branches in Europe.

Mr. Andrew M. Fairlie has accepted an appointment as chemical engineer with the reorganized Tennessee Copper and Chemical Corporation, whose works are at Copperhill, Tenn.

Mr. Wm. H. Gaines is operating an electrolytic zinc plant for the Basin Salvage Co., Basin, Mont. The work is at present in the experimental stage, and several new ideas are being tried out.

Mr. Carl M. Hansen, widely known through his activities in connection with accident prevention, compensation and casualty insurance, as chairman of the Committee for Accident Prevention and Workmen's Compensation of the National Association of Manufacturers. Mr. Hansen, who is the author of "Universal Safety Standards," a work of thirteen volumes, has been a frequent contributor to technical journals on subjects relating to compensation, prevention and occupational diseases, as well as related subjects. He is a member of the American Society for Mechanical Engineers, American Statistical Society, Casualty, Actuarial and Statistical Society of America, and several other scientific bodies. He was born in Denmark and received his early training in that country and Germany. Coming to America in 1903, at the age of twenty-three, he entered the construction department of the Dominion Iron & Steel Company, Sydney, Cape Breton, going from there to Newfoundland as mechanical engineer for a Newfoundland mine operating syndicate; thereafter he was associated with the Atlas Engine Works at Indianapolis, Ind. On account of his interest in methods of handling work accidents in this country and in Europe, he devoted special study to this subject and became successively connected with several casualty insurance companies.

Professor D. D. Jackson has been designated acting head of the Department of Chemical Engineering, Columbia University, to serve in place of Professor M. C. Whitaker, absent on leave.

Mr. K. L. Kithil, formerly connected with the Bureau of Mines, is now general manager of the Schlesinger Radium Co., of Denver, Col.

Mr. P. M. McHugh, general sales manager of the Dorr Company, has left Denver for a three weeks' vacation. After spending three or four days in St. Louis on business, Mr. McHugh will spend the rest of his furlough in the South.

Mr. W. H. McKenna, vice-president of the Vanadium Alloys Steel Company, Pittsburgh, Pa., accompanied by Mrs. McKenna, has started on an extensive pleasure tour of Japan and China.

Mr. S. M. Marshall has severed his connection with the Southwark Foundry & Machine Company, of Philadelphia, to accept a position with C. P. Perin & Co., consulting engineers, 3 Rector Street, New York.

Professor F. J. Metzger of the Department of Chemical Engineering, Columbia University, has resigned his position to accept the position of manager of chemical development with the Air Reduction Company, 120 Broadway, New York. Professor Metzger will assume his new duties Feb. 1.

Mr. O. C. Ralston of the Utah section of the Bureau of Mines recently passed through Denver on his return to Salt Lake City.

Mr. C. J. Ramsburg, vice-president of H. Koppers Company, at a joint meeting of the Franklin Institute and the Philadelphia Section of the American Society of Mechanical Engineers, Feb. 6, will read a paper entitled "By-Product Coke and Coking Operations." The paper will be illustrated by lantern slides and a moving picture film showing the operation of a by-product coke plant.

Mr. Dudhy Shaw is now engineer with the Air Reduction Company, 120 Broadway, New York. Mr. Shaw was formerly engineer for the Davis Bournonville Co., but left them to design and install a complete hydrogenating and compound plant. This plant was duly constructed in Austin, Tex., under the name of the Walker Refining Co., and though small was very complete, using Diesel engines for prime movers, and with direct connected generators furnishing current for the electrolytic oxygen and hydrogen cells.

Mr. R. K. Stockwell, who has been chief engineer and superintendent of construction for the Braden Copper Company at Raucaque, Chile, for the past five years, will open a Western engineering and sales office of the Robins Conveying Belt Company in Salt Lake City, Utah.

Dr. John E. Teeple, consulting chemical engineer, New York City, has been appointed associate in chemical engineering, Columbia University, and will at once assume charge of the courses in chemical works management, advanced industrial chemistry and chemical engineering.

Obituary

William Ainsworth, prominent manufacturer of precision instruments, died at his home in Denver on January 1, after a sudden attack of pneumonia, at the age of 67. Mr. Ainsworth has been a resident of Denver since 1877 and was well known in the chemical and metallurgical circles all over the country. The analytical and assaying balances of his design rank among the best used in the arts.

Mr. Archibald Colville, chairman of the directors of David Colville & Sons, Ltd., large English iron and steel manufacturers, died at The Moorings, Motherwell, on Dec. 11, 1916.

Book Reviews

Diseases of Occupation and Vocational Hygiene. Edited by George L. Cober, LL.D. and M.D., and Wm. C. Hansen, M.D. 918 pages. Price \$8.00. Publishers, P. Blakiston's Son & Company.

The intelligent study and prevention of occupation diseases has received a great help and support in this voluminous work. The authors have covered the field completely and have, besides, included a copious number of references. It is a volume which should be placed in every works manager's library, be it a chemical industry or any other industry. The book is one that is well needed to-day in the modern tendency of protecting employees against conditions by which their health and future happiness are impaired.

The Engineer in War. By P. B. Bond. 187 pages. McGraw-Hill Book Company, Inc.

With the strong interest taken to-day by laymen in all walks of life in military matters, this book should offer an interesting, as well as valuable source of knowledge. It is as non-technical as an extremely technical subject can be, and with its extensive glossary of military terms and its interesting and excellent illustrations, will furnish every engineer and non-engineer interested in military engineering, an excellent fount of information.

The Physico-Chemical Properties of Steel. By C. A. Edwards, D.Sc. Octavo (15 x 22 cm.), 229 pages, 181 illustrations. Price \$3.50. London: Charles Griffin & Co., Ltd.; Philadelphia: J. B. Lippincott Company.

The author is professor of metallurgy in Sheffield University. The book is a mixture of good and indifferent. The preface speaks of very complete references being given, but the book in detail does not bear this out; e.g. Burgess' work on the critical points of iron, done at the U. S. Bureau of Standards, is not mentioned. There are three lines about the electrical resistance of iron, and no data given. But solidification of ingots, deformation and strain in working, slip-bands, and chemical and physical constitution are handled in a masterly way. It is a book for the specialist, but not entirely uniform in treatment or up to date—for which latter item present disturbed conditions in scientific literature may be some excuse. **Elementos de Electroquímica.** By V. de Vivaldi-Coaracy. 12 x 19 cm., 218 pages. Official publication of the Electrotechnical Engineering School of Porto Alegre, Brazil.

Professor Coaracy is known in South America for his brochure on Technical Instruction in the United States. In this small book he discusses very clearly the fundamental principles of electrolysis, the theory of electric batteries and accumulators. For Brazilian students reading only Portuguese this will be a welcome book, opening to them the gateway to further studies in electrochemistry.

CURRENT MARKET REPORTS

The Iron and Steel Market

What has occurred marketwise in the past fortnight has been a development in thought rather than in action. Buyers are not conducting themselves differently than formerly. They are very reserved, in the case of both pig iron and finished steel products, about making any commitments beyond the middle of the year, while they show at least as much insistence as formerly with respect to earlier deliveries, continuing to exert pressure upon the producers to make deliveries, in case they have already bought, or seeking fresh tonnages when they have not.

On the whole it is a quiet market in pig iron and steel, as it has been since the middle or fore part of December. Such quietness is always to be expected at the holiday period, but is hardly to be expected during the second half of January. The development in thought during the past two or three weeks has been along the line that the steel mills are not likely to be under pressure indefinitely, but rather that the amount of business already booked comes close to being a measure of trade prospects in general.

The possibility of an early termination of the European war, entertained for several weeks after the German suggestion of Dec. 12, having disappeared, the trade has been able to proceed upon the assumption that

the war is to end either late this year or at some later time and in the minds of many this reduction in the uncertainty has tended to clear the prospect immensely, on account of the coincidence that granted an indefinite continuance of the war these observers expect the pressure upon the steel industry to decrease toward the end of this year. The argument in favor of this view is that on account of the ocean shipping situation iron and steel exports must decrease while eventually domestic consumption will be restricted by the high prices, and meanwhile the productive capacity is being increased. This view is held by many buyers if not the great majority. Its correctness is not admitted by all sellers or even a majority. It is admitted that exports are likely to decrease but the suggestion is made that the decrease will be brought about by increased pressure at home for steel. Undoubtedly that is the correct analysis for the next few months, for steel is growing still scarcer, but there is no great warrant for a belief that domestic requirements for steel will be greater in the second half of this year than in the first half.

EXPORTS

Iron and steel exports increased almost continuously until September, 1916, when the total exports reported by weight amounted to 643,767 gross tons, comparing with 307,656 tons as the best record before the war, made in May, 1912. In October there was a decrease of 5 per cent and in November a further decrease of 9 per cent. Since November the losses in merchant vessels through submarine and other war activity have been at a greater rate than formerly and there is no prospect of anything but continued further decreases in the amount of merchant shipping available. The intense activity at all shipyards does not suffice to make up for the losses. The export statistics as commonly quoted are not illuminating for the reason that they are statistics of declared values, not of quantities.

DOMESTIC DEMAND

The record of domestic consumption of steel during this movement has been full of surprises. It used to be considered that there was a "safe" level for steel prices, beyond which they could not advance without consumption being curtailed on account of the cost. Approximately speaking this level was reached at the end of 1915, and at that time the mills were sold up to about the middle of July, 1916. They have continued under great pressure for six and a half months longer, showing that the consumption was not noticeably retarded by the passing of the traditional. It does not follow, however, that there is no price level at which consumption would be curtailed sufficiently to make an impress upon the mill position. There is no means of ascertaining the average price of the steel now being shipped but there is one concrete fact that is suggestive. On July 1, 1916, the mills had on their books a tonnage of business, which if suitably distributed among the different finished products would have carried them to this present date, and prices at that time were on an average \$14 per net ton below present prices. Some of the business now being filled was booked prior to July 1 and some of it was booked later. It is still to be determined whether full consumption would continue were all consumers forced to pay present prices, and the common view among consumers is that it would not. It is to be observed that the amount of strictly "war steel" being shipped is not a large proportion of the total output. It is believed that after the war there will be certain fresh demands for steel, at the more moderate prices that will then prevail, and such a view cannot well be harmonized with an idea that present domestic consumption is to

continue indefinitely, during the war, at the present high rate, for if so the demand after the war would be still greater and steel prices ought to advance instead of decline. Such a suggestion may appear rather far fetched but it is worth while to look at the matter from this angle. If there is good reason, and there certainly is, to expect a good demand for steel after the war, it is absurd not to consider the restrictive influence that war prices must exert on some lines of consumption.

TRANSPORTATION

The industry is suffering still more severely from lack of full transportation facilities. Coke shipments from the Connellsville region are about 25 per cent less than the requirements of the blast furnaces tributary to the region. At some groups of furnaces one or more stacks are banked and the remainder pushed to capacity, while other producers slow down their operations. At many furnaces, indeed, there has not been enough coke with which to bank. The curtailment in pig iron production does not appear to have directly caused any decrease in steel output, nor has it affected the pig iron market, except to bring out some insistent inquiry for small lots of malleable and foundry iron for immediate shipment to consumers dependent upon western Pennsylvania, valley and lake front furnaces.

Shipments of steel, particularly in the Pittsburgh and valley districts, have been curtailed by a few per cent on account of the railroads being unable to move loaded cars freely. Car shortages are not so much in evidence. The strenuous efforts made by the railroads to move empty cars appear to have been more or less successful but trouble crops out in this new manner. Some mills which a month ago could not secure enough empties for loading are now confronted with the danger that if they load cars they will be charged demurrage because they are not taken away.

Prices have been practically stationary all along the line. Effective January 23 the Steel Corporation subsidiaries advanced their prices on shapes and plates by \$3 a ton, to 3.25c. for shapes and 3.75c. for plates, but all such quotations are practically nominal, being for "shipment at mill convenience." Buyers feel that they need not concern themselves with deliveries so far in the future that it would be convenient for mills to make them.

Non-Ferrous Metal Market

Thursday, Jan. 25—Copper is higher on account of a scarcity of supplies, and tin has advanced in an unsettled market. Lead is virtually unchanged but supplies are scarce, spelter is slightly higher but the market has been quiet. Antimony has been in good demand and is higher.

Copper.—The large producers have not been offering any copper for sale before the middle of the year and the market has been dull. The refinery of the American Smelting & Refining Company at Perth Amboy, N. J., has been closed for almost two weeks on account of a strike, which is understood to have been settled now. This strike and the freight congestion in various parts of the country have tended to shorten supplies somewhat. Electrolytic is quoted at 32.50 to 33.00 cents with Lake at 31.50.

Tin.—Cables from London have been held up and naturally the market here has been in more or less of a confused state. There has been a fairly good demand for prompt deliveries but sellers have been shy. Straits tin is now quoted at 45.50 cents, an advance of about 3 cents in the last two weeks. There is a scarcity of

Banca tin reported. Arrivals to date this month are 2650 tons.

Lead.—This market has been very dull, but supplies are scarce and the independents are asking up to 8.00 cents with the trust price unchanged at 7.50.

Spelter.—Spelter is about $\frac{1}{2}$ cent higher, but the market has been quiet. The difficulty of obtaining freight room is holding back export business. Producers have not shown any desire to push domestic sales and are banking on a larger export business to take care of the enormous production. The quotation for prompt shipment is 10.00 cents at New York.

Other Metals.—Antimony is in good demand and has jumped up 2 cents to 16.50. Aluminium is quoted at 56.00 to 60.00 cents, magnesium \$3.00 to \$3.50, electrolytic nickel at 50.00 cents, cadmium at \$1.50, quick-silver \$80.00, platinum \$90.00, cobalt \$1.50 and silver at 76 $\frac{1}{2}$ cents.

Chemical Market

Coal tar products attracted possibly more attention than any other branch of the industry during the past fortnight. There appear to be an important number of consumers who are anxious to cover and have been taking advantage of any possible loopholes in the market and closing whenever there was a possibility of a good buy.

Benzol has been subject to quite a persistent inquiry. A number of large consumers are in want of supplies and must have them for nearby deliveries. The general position has been a firm one for any delivery up to March. Beyond March, the position is rather uncertain, as new productions will reach the market at that time, making the general situation a peculiar one. During the two weeks spot business ranged from 56c. to 58c. with contracts over the year averaging 51c. to 52c. One large contract was placed by one of the coke companies on the basis of 44c. for deliveries over the year but it is generally admitted that only a favored buyer could work a price such as this. The stipulation was that the benzol was not to enter into the munition trade, as the selling company is German owned, and will not sell for other than dye manufacture.

The **toluol** situation has been firmer than the benzol one. For spot and nearby delivery it has not been possible to do better than \$1.75 to \$1.80 and on contract \$1.45 to \$1.50 is named. A large munition concern that lately purchased on a very low basis has endeavored to cover again at a price about approximately equal to that upon which their last purchases were made. At the moment of writing they have not been able to secure offers within 25c. of their bid.

Aniline oil has been another coal tar product that has firmed up considerably, principally due to the heavy export inquiry from England. The market has at times reached below the 20c. level but to-day there is but little likelihood of securing important amounts under 25c. Even with the higher market, selling prices allow of a very narrow margin of profit to makers considering the present price of benzol and acids.

In contrast the market for **phenol** has been weak and the leading makers have all lowered their asking rate with but little actual consuming inquiry noted.

In the intermediates, **H acid** (the amidonaphthol disulphonic acid 1:8:3:6) continues to attract much attention. There are about five producers, two of which make for their own consumption. The product is an extremely difficult one to make and complicated machinery is used. It is the intermediate for the production of **direct black**. Contracts are nominally quoted at \$2 per pound for long terms basis 80 per cent.

Of the pharmaceutical chemical salts, **beta naphthol benzoate** attracts much attention owing to the impor-

tant export inquiry. There are about five producers on a commercial scale. Spot prices range from \$17 to \$20.

Alpha-naphthylamine is attracting considerable attention and as the output is a restricted one well under control a number of interests in the trade are contemplating its manufacture.

A production of **benzoyl chloride** is announced. This is an important intermediate for the manufacture of **malachite green**. It is quoted at \$18 on spot and about \$16 on contract. **Benzyl** and **benzal chlorides** are being made by several producers, the first named selling at \$3 and the latter at \$5.00. **Carbonyl chloride** and, of course, **Michler's ketone** is now produced in this country in a small way.

As the Bayer patents covering **aspirin** will expire next month, an active preparation is being made openly to manufacture the product. Of course, there has been a production of **acetyl salicylic** for some time and sold in a quiet way, but there will probably be a dozen makers ready for business as soon as the Bayer patents run out. Supplies of **acetic anhydride** are scarce, however, and these new makers will be up against a raw material problem.

In heavy chemicals, the interval has been a rather quiet one. On the spot **soda ash** is perhaps five points lower than two weeks ago. Some business has passed but of course with such an enormous production as is noted at the moment business must pass. **Caustic soda** is easier, resale lots, perhaps, keeping the market down to a level to which there was no legitimate title. Makers are well sold up and the export movement is really tremendous. For contracts, makers hold out at about the same prices prevailing a fortnight ago.

Bichromate of soda has taken a sharp drop, despite the efforts of leading interests to maintain the market. This market has been practically in the hands of one firm for many years past but owing to new inducements held out by high prices and an increased production of chrome ore at home there are now seven producers. Three of these manufacture for their own use. **Bichromate of potash** remains quite steady.

Cyanides of domestic manufacture continue high with practically no supplies available, particularly the potassium base. Japanese offers continue persistent and doubt is expressed whether present values will hold indefinitely in face of these offers.

Chlorates are about unchanged and the new manufacturers of this product are seemingly marketing their output without forcing values downward. **Copper sulphate** has been in fair request and values have not undergone substantial change.

General Chemicals

WHOLESALE PRICES IN NEW YORK MARKET JANUARY 25, 1917

Acetone, Drums	per cent.	100 lb.	22 $\frac{1}{2}$	23
Acid, acetic, 28 per cent.	100 lb.	3.25	3.50	
Acetic, 56 per cent.	100 lb.	7.00	7.10	
Acetic, glacial, 99 $\frac{3}{4}$ per cent	carboys.	10 lb.	22	22 $\frac{1}{2}$

INDUSTRIAL

Financial, Construction and Manufacturers' News

Financial

A syndicate composed of the principal banking and business interests of Norway has purchased the seven-eighths interest in the Arctic Coal Company, held by J. M. Longyear and Frederick Ayer, of Boston. The deal included some minor properties including ships, but the major properties are the famous Spitzbergen mines, located on the Spitzbergen islands in the Arctic that lie north of Norway and only about 700 miles from the North Pole. A new company has been formed with a capital of 10,000,000 crowns (\$2,650,000).

The Arctic Company's property covered about 170 square miles. Most of the work completed has been of a development nature and the output has not amounted to much more than 200,000 tons. Exploration showed many valuable and extensive veins of semi-bituminous coal, one alone disclosing 100,000,000 tons.

All Points Trading Company, Inc., New York. Capital \$5,000. Incorporated to manufacture drugs, medicines, paints, chemicals, oils, dyestuffs, by G. V. Sheridan, S. D. Muney and A. L. Berman, 56 West 110th Street.

The Alto Cotton Oil & Mfg. Company, Alto, Texas. Capital \$25,000. Incorporators: H. H. Berryman, J. E. Waters and T. Arant.

The American Abrasives Company, has been incorporated at Dover, Del., by E. G. Neiss Wayne, L. L. Voigt, George M. Harton, all of Pittsburgh.

The American Magnesium Corporation, Niagara Falls, N. Y. has been incorporated with a capital of \$200,000, in New York State. The charter states that the company is authorized to manufacture magnesium, barium, calcium and other metals. The directors are E. W. Burdick, L. J. Hallenbeck and J. J. Devereux, all of New York.

Aroostook Pulp & Paper Company, Boston, Mass. Capital \$500,000. Incorporators: A. N. Blandin, George S. Lewis, 141 Milk Street, and S. F. Johnson.

Bald Hill Mining Company, Seattle, Wash. Capital \$1,000,000. Incorporators: A. C. Smith, G. Mathew, L. Stadler, E. W. Winslow and B. T. Ulrich.

The Blackstone Oil and Paint Company, Cleveland, Ohio. Capital \$10,000. Incorporators: G. T. Baudouin, W. S. Scarus, J. E. Robinson, A. F. Gaughin and T. A. Gillespie.

Bristol Power, Pulp & Paper Company, Wilmington, Del. Capital \$1,000,000. Incorporated to manufacture wood pulp and paper, by K. M. Dougherty, M. C. Donohue and F. Giles, Wilmington, Del.

Burdett Oxygen Company, Chattanooga, Tenn. Capital \$100,000.

Columbia Bronze Corporation, Freeport, N. Y. Capital \$150,000. Incorporated as founders, welders, etc., by L. H. Rose, H. W. Bennett and J. A. Sutter, East Orange Parkways.

Congress Copper Company, Kittery, Me. Capital \$2,500,000. Incorporated to operate mines and mineral lands.

Connecticut Smelting & Foundry Corporation, Wilton, Conn. Capital \$300,000. Incorporated to conduct mills for the treating of metals.

Cornell Pulp Reduction Company, Inc., Watertown, N. Y. Capital \$50,000. Incorporated to deal in pulp, hardwood, fibrous products. Incorporators: W. N. Cornell, G. H. Burna and P. B. Hudson, Watertown.

Coeur d'Alene Federal Mines Corporation, Portland, Ore. Capital \$1,000,000. Incorporated to do mining business by B. E. Sanderson, E. V. Mann, Charles D. Booth, D. and L. Mfg. Company, New York. Capital \$10,000. To manufacture metal specialties. Incorporators: J. H. Miller, M. Dohrlik and M. Lansky, 2322 Crotona Avenue, Bronx.

H. T. Dakin Paper Company, Waterbury, Conn. Capital \$55,000. Incorporated to manufacture and deal in all kinds of paper, by R. Dumouchal, A. H. Anderson and R. S. Walker.

Delta Beet Sugar Corporation, New York. Capital \$200,000. Incorporated to manufacture sugar beets, sugar, by-products, by T. D. Adams, M. G. Laux and A. H. Curtis, 43 Exchange Place.

Diversey Foundry Company, Chicago, Ill. Capital \$10,000. Incorporators: Catherine M. Rowbottom, James J. Rowbottom.

Eastbrook Copper Company, Delaware. Capital \$100,000. Incorporated to do a general mining business by G. J. Powell, E. W. Stevens, Gwendolyn J. McNeil, all of New York.

The Electric Smelting Corporation, Baltimore, Md. Capital \$100,000. Incorporators are Attorney Adolph Schoenels, J. F. Dirzuweit and Katharine Dirzuweit, of Baltimore.

J. P. Eustis Mfg. Company, Cambridge, Mass. Capital \$103,000. Incorporated to deal in metals by J. P. Eustis, Newton, Mass. Treasurer, Frank Owen White, Brookline, Mass. clerk.

Fall Mountain Pad & Paper Company, Vermont. Capital \$10,000. Incorporators: F. L. Thompson, F. A. Moore, H. B. Underhill, Wellows Falls and J. W. King, Walpole, N. H.

Farbenfabriken of Elberfeld Company, Paterson, N. J. Capital \$125,000. Incorporated to manufacture chemicals, dyes, etc.

Flax Fiber Company, Helena, Mont. Capital \$50,000. Incorporated to engage in the manufacture of fiber. Incorporator: George Person and others.

Fritzsche & Kleason, Buffalo, N. Y. Capital \$10,000. Incorporated to a paint, dye and varnish business. Incorporators: H. L. Jauch and R. J. Kimball.

Globe Chemical Company, Broadway, Jersey City. Capital \$3,000. Incorporated to manufacture chemicals. Incorporators: H. W. F. Lorenz, A. Proven, J. F. W. Lorenz and L. J. Brown, Jersey City.

Good Faith Oil & Gas Co., Dover, Del. Capital \$240,000. Incorporators: Julia S. Jones, A. B. Blagoe, H. N. Fembelton, all of Dover.

Hattiesburg Pulp & Board Company, Fenwick, La. Capital \$125,000. Incorporated to manufacture wood and paper.

The Henle Wax Paper Mfg. Company, Inc. Capital \$50,000. Incorporated to manufacture paper, pulp, cloth and textile fabrics. Incorporators: R. Vallantine, A. Schmitt and C. O. Maas, 57 West 75th Street.

Hudson Bay Paint Company, Inc., Buffalo, N. Y. Capital \$25,000. Incorporated to manufacture paint and varnish, by G. Staumacher, 1616 Delaware Avenue: A. A. Hoestermann, 69 Moullier Street, and W. J. Lavery, 19 Kulline Street, Buffalo.

Ideal Acetylene Company, Inc., Delaware. Capital \$400,000. Incorporated to manufacture and sell acetylene and gas generators. Incorporators: H. E. Latter, N. P. Coffin, Wilmington, Del., and C. M. Igner, Elkton, Md.

Ideal Leather Company, Inc., New York. Capital \$10,000. Incorporated to manufacture leather and chemicals, by James V. Padula, G. Compatori, Newark, and Jos. Vicariat, Bellevue.

Imperial Chemical Corporation, New York. Capital \$750,000. Incorporated to manufacture coal tar products, explosives, etc., by H. S. Perrigo, 660 St. Nicholas Hanson, Place, New York City, and S. C. T. Dodd, 1918 Avenue H, Brooklyn.

Jersey Consolidated Copper & Gold Mining Company, Wilmington, Del. Incorporated to do mining business. Capital \$100,000.

K. & T. Chemical Corporation, New York. Capital \$35,000. Incorporated to manufacture chemicals, dyestuffs, oils, paints, etc., by W. B. Root, 1437 Sterling Place, Brooklyn: E. L. Karliner, 939 Simpson Street, New York City: F. J. Byrne, 529 Broadway, New York.

Keystone Leather Chemicals Company, Delaware. Capital \$25,000. Incorporated to manufacture chemicals and chemical compounds.

Langan Paint Company, Kewanee, Ill. Capital \$40,000. Incorporators Jas. M. Langan, C. A. Langan and Jas. F. Langan.

The Lehigh Valley Facing Company, Wilmington, Del. Capital \$100,000. Incorporated to manufacture foundry facings. Incorporated by K. M. Dougherty, M. C. Donohue and F. Giles, Wilmington, Del.

McAuliffe Paper Company, Inc., Burlington, Vt. Capital \$50,000. Incorporators: W. A. McAuliffe, Ottawa, E. L. and H. J. McAuliffe, of Burlington.

Maratino Coating Corporation, Wilmington, Del. Capital \$50,000. Incorporated to manufacture and deal in chemicals.

Matthews Steel Co., Newark, N. J. Capital \$50,000. Incorporated to deal in iron and steel by J. Swenson, J. S. Swenson and H. Todd, Newark.

Metasap Chemical Company, 10-20 Essex Street, Harrison, N. J. Incorporated to sell chemicals. Incorporators: J. Phillips, 25 Hillsale Avenue, Newark; R. Biehringer, 112 Second Avenue, Newark; W. E. Wachsman, 102 Lord Avenue, Bayonne, and C. P. Sulick, 313 Clifton Avenue, Newark.

Moore Paper Mills Corporation, Albany, New York. Capital \$50,000. Incorporated to manufacture paper and boxes. Board by William P. Moore, Charles G. and Blanche S. Moore, of Buffalo.

The Ohio Pattern, Works & Foundry Company, Cincinnati, Ohio. Capital \$200,000. Incorporators: Jos. E. Hausfeld, Amelia S. Hausfeld, Ed. E. Hausfeld, Victor E. Tresise, Grace L. Tresise and Fannie Pearl Tresise.

Outwear Leather Corporation, New York. Capital \$350,000. Incorporated to manufacture rubber articles, by M. T. Kelly, W. Phinney and G. H. Wyckoff, 115 Broadway.

Parsons Bar Company, Charlotte, N. C. Capital \$100,000. To deal in dyestuffs and chemicals. Incorporated by W. A. Parsons, E. B. Parsons and J. M. Barr, of Charlotte.

Patent Record Publishing Co., Inc., New York. Capital \$75,000. Incorporated to publish, print, deal in mail, paper, products, cloth, drugs, photographs, etc. (type apparatus) by H. L. Varian, E. H. Ball and W. D. Kemp, 459 Fifth Avenue.

The Pequotian Rock Valley Paper Company, Morristown, N. J. Capital \$140,000. Incorporated to carry on the manufacturing business at Butler, by Isabel C. White, Frank S. White, Walter C. White and Joseph C. White.

The Phillips Lead & Supply Co., Providence, R. I. Capital stock increased from \$30,000 to \$100,000.

Quick-Kleen Chemical Company, Inc., Brooklyn, N. Y. Capital \$5,000. Incorporated to manufacture soap, perfumery, oils, gases, chemicals. By C. H. Hoag, D. Deminger, J. A. Eadie, 505 De Kalb Avenue, Brooklyn, N. Y.

Royal Dye Works, Inc., New York. Capital \$10,000. Incorporated to dye furs, skins and to make goods. Incorporators: L. Scorsons, F. P. Kamholz and W. Koenig, 25 Echo Road, New Rochelle.

Sedalia-Lebanon-Novata Lead and Zinc Company, Novata, Ark. Capital \$100,000. Incorporated by A. C. High, 1000 N. C. Mayfield, Lebanon, Mo., and J. W. Palmer, Sedalia, Mo.

Seneca Copper Corporation, New York. Capital \$1,000,000. Incorporated to do mining, milling gold, silver, copper, etc., products and by-products, deal in agricultural products, drugs, furniture, machinery, supplies, etc., by F. C. Fischer, chemist, and K. A. Duffy, 15 Broad Street, New York City.

Sinclair Gulf Corp., Albany, N. Y. Capital \$5,000,000. Incorporated to carry on a mineral oil and gas business.

Tadaco Turpentine Co., Mobile, Ala. Capital \$5,000. Incorporated to engage in the general timber and turpentine business in south Alabama. Incorporators, T. J. Taylor, S. Lowenstein, A. Lowenstein, H. C. Taylor, R. E. Crum, J. W. Gray, D. Dumont and B. C. Fick.

Triangle Leather Goods Corp., New York. Capital \$5,000. Incorporated to manufacture leather novelties. Incorporators, M. Moskowitz, F. and J. Hart, 223 East 83rd Street.

Troy-Kalspell Mining Company, Troy, Idaho. Capital \$300,000. Incorporated to take over the 15 claims of Wood & Hogan, 12 miles west of Troy, in Idaho.

Umans Dye Works, Inc., New York. Capital \$16,000. Incorporators, E. London, R. and H. Umans, 215 W. 11th Street.

The United States Smelting & Refining Co. has purchased a controlling interest in the Big Four Exploration Company, which handles 800,000 daily of old mill dumps in Utah. The Big Four company's office is in Newhouse.

Universal Leather Company, Newark, N. J. Capital \$50,000. Incorporated to manufacture and deal in leather goods. Incorporated by Walter F. Gins, Stanleigh F. Friedman, New York; Charles B. Sutter and Meyer E. Ruback, Newark, N. J.

The Wisner Oil Company, Bartlesville, Tex. Capital increased from \$100,000 to \$200,000.

Wright Chemical Corporation, Newark, N. J. Capital \$100,000. Incorporated to manufacture chemicals, dyes, dyestuffs, acids, alkalies, salts and paints. Representative Allan E. Crocker 93 Park Row, New York.

Yellow Pine Paper Mill Co., Orange, Tex., has increased its capital from \$500,000 to \$1,000,000.

Construction and Operation

Arizona

BISBEE.—The new smelter of the United Verde Extension Company is expected to be ready in four months from the time work is actually commenced. Until this smelter is completed, the Extension Company will continue to market its ores at Douglas and Humboldt.

Arkansas

FORT SMITH.—The Fort Smith Smelter Company will build a \$350,000 lead and zinc smelting plant to contain 6,000 retorts.

California

JACKSON.—Messrs. Simmonds & Latham of Melones will build a \$15,000 cyanide plant near Jackson to work tailings of the Argonaut mine. There are about 200,000 tons of this material available. A flotation process may be installed later.

LONG BEACH.—Mr. Cyril E. Bratton, of Seattle, plans the erection of a \$150,000 plant at Long Beach for the manufacture of strontium nitrate. The proposed plant will be located just west of the California Glass Insulator Works near the Southern Pacific Main Line between Long Beach and San Pedro. It will be operated as a Bratton Manufacturing & Chemical Company.

LOS ANGELES.—The R. W. Pridham Paper Mill will make repairs and alterations costing \$50,000. The plant was recently damaged by fire.

SANTA BARBARA.—The news that a potash factory would be established at Summerland, near Ortega Hill, has aroused millionaire residents of exclusive Montecito. The opposition is based on the contention that the benefits to the community would be small in comparison with the objection of cutting the kelp which would leave the coast open to the full force of the storms, resulting in heavy damage.

Colorado

DELTA.—The Holly Sugar Company plans the erection of a \$1,500,000 factory at Delta, Colorado and also plans to purchase another factory at Grand Junction, tremendously increasing its beet sugar output.

DENVER.—The Stearns-Roger Manufacturing Company has been awarded the contract for the construction of a \$1,500,000 beet sugar factory to be erected at Delta, Utah.

Connecticut

FAIRFIELD.—The Hamilton & De Loss Company, recently organized, with \$300,000 capital, has secured a site for a factory near the Handy & Harmon plant and plans the erection of a \$100,000 structure. The company will manufacture metal parts and will use scrap silver, steel, brass and copper, and expects to employ from 500 to 800 hands. H. H. Hamilton, President of the Whiting Manufacturing Company, is president of the new company, and H. H. De Loss, president of the Handy & Harmon Company, is also interested.

HARTFORD.—The Russell Company is erecting a new dye house, 34 x 80 feet, two stories high.

MERIDEN.—The Quanguo Cut Glass Company, of Hawley, Pa., has purchased the entire equipment from the glass plant of Hall & Callahan in this city and will ship it to Hawley.

NEW HAVEN.—The Pennsylvania Seaboard Steel Corporation will erect a one-story steel structure to cost about \$25,000. The contract has been let to the Belmont Iron Works of New York.

STAMFORD.—The Stamford Rolling Mills Company has awarded to the Austin Company the contract for a new building to be used for smelting.

District of Columbia

WASHINGTON.—The Department of Agriculture has perfected a citrus fruit peeling machine and developed processes for pressing and chemically treating the removed peel whereby they believe an oil equal in quality to the imported oil may be produced at a cost to enable competition with the foreign product. The new process aims to make use of low-grade oranges heretofore wasted.

Florida

PENSACOLA.—The Pensacola Fertilizer and Oil Company, with headquarters at 21 Spruce Street, New York City, will con-

struct an oil and fertilizer plant on a 90-acre site at Grassyview. Actual work will be started in February. The capacity of the plant will be about 100 tons of fish scrap per day and about 200 barrels of oil.

Illinois

ROCK ISLAND.—The paint factory of the Illinois Oil Company was expected to be completed during the latter part of January. The factory will be used for the mixing of oils and pigments in the process of manufacture of paint. The building when completed will cost \$50,000. Mr. P. P. Welch is president of the company.

Indiana

TERRE HAUTE.—The Grasselli Chemical Company is now building a large chemical and zinc smelting plant in the north of the city, which will be completed by the first of 1918. It will represent an investment of \$3,000,000 and one large building will be 250 x 300 feet. Actual work will be started about the middle of the coming spring.

TERRE HAUTE.—The Root Glass Company will rebuild the factory which was destroyed by fire in December.

Iowa

CEDAR RAPIDS.—The Holland Furnace Company has completed negotiations with the Chamber of Commerce of Cedar Rapids, Ia., and will erect a new factory in that city.

DUBUGUE.—The Adams Company will erect a large addition to its plant on Fourth Street during the coming year. The new building will house the machine shop. The company operates a foundry and manufactures hardware specialties and machinery.

Kansas

ELDORADO.—A new \$300,000 refinery is planned by the Midland Refinery Company, which has recently been chartered by V. G. Skully, of Tulsa, Okla., and W. Irving Osborne, of Chicago.

Kentucky

IRVINE.—The Cumberland Torpedo Company announces the establishment of a factory at Miller's Creek for making nitroglycerin to be used in shooting oil wells.

Maine

BANGOR.—The Texas Oil Company has purchased from I. M. Pierce and W. A. Finnigan a parcel of land on the Penobscot River on which tanks and building will be erected for making Bangor the distributing and commercial center of eastern and northern Maine.

GARDNER.—Major Lamb has received a letter from a large Western company making inquiries regarding location for a sulphite pulp mill and asking for assistance from the city.

Maryland

BALTIMORE.—The Electric Smelting Corporation, a new company formed with a capital of \$100,000, will undertake the manufacture of electric furnaces for melting copper, brass and other nonferrous metals, and for manufacturing alloys. The incorporators are Adolph Schoenels, John F. Dirzuweit and Katharina Dirzuweit, all of Baltimore.

Michigan

MUSKEGON.—The Lakey Foundry Company will erect a large modern foundry plant which will more than double its present output. The present foundry produces about 40 tons of castings per day. It is planned to have the new structure completed by July 1.

Montana

BIGFORD.—Glacier Park Pulp & Paper Co. will erect paper mill in this vicinity, and for this purpose company has been organized at St. Paul with \$100,000 capital. S. S. Gillette, pres., 327 Nicollet Ave., Minneapolis.

Nevada

ELY.—The Consolidated Copper Mines Company will build another 500-ton unit at its Giroux mill. The first 500-ton section will be placed in commission about January 15.

New Jersey

CAMDEN.—Fire caused \$50,000 damage to the plant of the General Chemical Company on Cooper River. The pottery, office, laboratory and pottery storehouse were destroyed.

HARRISON.—Plans prepared for erection of addition at rear of Crucible Steel

Co. plant between Sixth and Seventh Sts.; cost about \$200,000.

JERSEY CITY.—The Globe Chemical Company, 163 Broadway, Jersey City, a new company capitalized at \$300,000, will increase its production of benzoic acid to 100 lbs. per day. Dr. Henry W. Lorenz is superintendent of the plant.

KEARNY.—General contract awarded by Egyptian Lacquer Mfg. Co. to Turner Construction Co., 11 Broadway, New York, for erecting on this building, 2-story, 160 x 92 ft., with L 30 x 40 ft.; one 2-story, 120 x 60 ft., office building; 1-story, 60 x 60 ft., and railroad trestle.

LINDEN.—The Ammo-Phos Chemical Corporation's new plant will cost \$200,000 and the Grasselli Chemical Company's factory additions will cost \$55,000.

NEWARK.—The North American Copper Company, 52 Vanderbilt Avenue, New York City, will erect a large copper refining plant on the Kearny meadows between the Hackensack River and Hackensack Avenue.

NEWARK.—The plant of Seaboard By-Products Coke Company is progressing nicely and is expected to be finished soon after the arrival of better weather.

NEWARK.—The Louis Sacks Iron Foundry has added a brick pattern storage building to the group of structures at Hamburg Place. The company manufactures semi-steel.

NEWFIELD.—Work is being rushed on the new glass factory at Newfield and it is expected a large force of men will be employed as soon as the plant is finished.

RIDGEFIELD PARK.—The Bergen Paper Mill will enlarge its plant and will increase its output by 50 per cent.

New Mexico

ALBUQUERQUE.—The J. G. White Engineering Corporation has been awarded a construction and engineering contract by the Senorito Copper Corporation of Senorito, N. M., in the Monticello District, 90 mi. northwest of Albuquerque.

The contract covers installation of a mill and power plant, a two-mile tramway, necessary mining machinery and equipment of the company's coal mine to produce fuel for the power plant. Initial installation will be for production capacity of a quarter million pounds of copper per month. Active work has been started and construction is being rushed in order to take advantage of the high price of the metal.

The mill and plant embody some unusual features enabling the production of refined copper at the mine and eliminating the necessity of transporting the ore. This will be accomplished by the Greenwall electrolytic method of leaching and electro-deposition.

New York

AUBURN.—The Cayuga Steel Company, Ltd., with a capital of \$300,000, is considering the selection of a site for a big factory in Auburn. The company is authorized to buy, lease, erect, equip and operate furnaces, mills, shops and plants for the production of, re-working, and manufacture of iron, steel and other metals and alloys.

NEW YORK.—The By-Products Company, 10 Broadway, New York City, is contemplating the addition to its plant of a boiler house at its plant on Shooter's Island, near Staten Island, to cost about \$125,000. A new tankage plant will also be erected at a cost of about \$150,000.

NEW YORK.—The Chemical Manufacturing Corporation, 200 Nassau St., will begin the manufacture of dyes about February 1. The president of the company is Spencer D. Embree.

SYRACUSE.—The Smet-Solvay Company plans to make extensive experiments and to take up the manufacture of intermediates and dyes. The company has begun the manufacture of salicylic acid and plans to take up other lines.

NIAGARA FALLS.—The American Magnesium Corporation, a new company, with a capital of \$300,000, will establish a factory at the far north end for the manufacture of magnesium. It is also authorized to manufacture magnesium, calcium and other metals. The directors are E. W. Burdick, I. J. Hallenbeck and J. J. Devereux, all of New York.

MONTICELLO, N. Y.—The Mont Color & Chemical Company has been formed to produce chemicals, intermediates and dyes from coal tar. Some equipment has been ordered but further purchases will likely be made in the near future. The company would like to receive catalogs from machinery and other houses. Mr. F. P. Brenner is manager.

Ohio

BELLAIRE.—Several of the glass factories in this section are experimenting with crude oil and coke on account of the gas shortage.

CANTON.—The United Furnace Company has started operations at its new blast furnace here. Its daily output is to be 450 tons. A by-product coke oven and benzol plant is also practically finished. The new furnace will supply hot metal to the United Alloy Steel Corporation.

CINCINNATI.—The Comfort Paper Company, recently incorporated with a capital of \$400,000, plans the erection of a large paper mill for the manufacture of book papers in the Millcreek Valley, not far from Cincinnati. The incorporators are George O. Comfort, of Kalamazoo, Mich.; M. J. Sullivan, of Cincinnati; William A. Stuart, of the Browne & Stuart Company; Charles E. Wing and Thomas H. Kelley.

CINCINNATI.—Plans being prepared by Ward Baldwin, consulting engineer, 809 Commercial Tribune Building, for erecting addition to Union Distilling Company's plant, Carthage; estimated at \$200,000.

LORAIN.—The United States Steel Corporation is said to be back of a \$200,000 land purchase here with the idea of erecting another steel plant.

Oklahoma

ALLEN.—The Crystal White Refining Company has recently increased its capacity from 300 to 1000 barrels a day.

Oregon

OREGON CITY.—The Hawley Pulp & Paper Company will shortly commence work upon its second big unit of the mill which it is erecting. The first unit has been completed and the machinery is now being installed. The total cost of this unit was \$1,000,000.

Pennsylvania

COATESVILLE.—The Lukens Iron & Steel Company will erect a new mill for the rolling of steel plates which will be the largest similar unit in the world. The new mill will be 17 feet wide, capable of rolling plates up to 192 inches in width. The two largest mills in the United States at present roll 152-inch plates and a 168-inch mill is the limit of the British Isles. Coatesville, with the extension of the Lukens Company and the expenditure of \$10,000,000 on company and the Worth Bros. plant, is rapidly forging to the front as a steel manufacturing center.

HARRISBURG.—Mr. L. M. Lawson, of Bridgeport, Conn., has recently been in Harrisburg on a visit to inspect a project for the growing and refining of sugar beets in this community. If possible a plant will be built with local capital.

JOHNSTOWN.—The Franklin plant of the Cambria Steel Company has broken ground for two new buildings to cost \$3,000,000. A car wheel plant to cost \$4,000,000 will also be built. Further extensions are expected but have not yet been officially announced.

MARCUS HOOK.—Some interesting figures on the growth of Delaware County last year are presented. New buildings were put up by the Benzol Products Company, General Chemical Company, Conolum Company, Viscose Company, Sun Oil Company, all in Marcus Hook, reaching an approximate cost of \$5,000,000.

SOUTH BETHLEHEM.—The Bethlehem Steel Company has announced that it will erect an Ingot and casting plant with a capacity of 500 tons a day. The foundry will be equipped with the very latest appliances and will cost \$750,000.

Tennessee

CHATTANOOGA.—The Lookout Paint Company, whose plant was destroyed by fire, will rebuild same and within thirty days expects to have temporary building erected and a portion of the plant put in operation.

Texas

HOT-SPRING.—A large tract of land on the Sabine-Neches Canal, between Beaumont and Port Arthur, has been purchased by E. L. Doherty, of California, who expects to erect a \$2,000,000 refining plant for refining oil.

Utah

SALT LAKE CITY.—Local capitalists interested in the Lake Cache Sugar Company have been selecting sites in Northern Utah for a new sugar factory. The company has purchased the Knight Sugar factory at Raymond, Canada, which will be moved to Utah.

Virginia

HOPWELL.—The Dupont Company has awarded contract to the Westinghouse Electric Company for a large electric generator for its new nitrogen plant under construction at City Point. The new generator will have a capacity of 25,000 horsepower.

Washington

PORT ANGELES.—Whalen Brothers, of Canada, are understood to have under consideration the erection of a large paper pulp mill in Port Angeles, Wash. The enterprise has been financed by Peabody, Houghteling & Co., of Chicago. Construction of the plant will begin about the first of February and will be finished in eight months. It is expected that their paper mills will be erected on Puget Sound in the near future.

SPOKANE.—The Berlin Dye Works plans the erection of an addition to its plant. Mr. Joseph Mackoff, proprietor, has left for Chicago to purchase new machinery.

TACOMA.—Owing to increased capacity at the plant of the American Smelting & Refining Company here (refineries nearly double in size), the company will erect a new stack for carrying off gas, etc. The new stack will be 350 feet high, 30 feet higher than the one at Butte, which now holds the record, and will be 25 feet in diameter at the top. The new stack will be equipped with a Cottrell precipitator for recovery of fine metallic dust. The present stack is equipped with this apparatus and from 10 to 15 tons of fume per day are recovered in this manner. The new stack it is expected to recover 30 to 40 tons per day.

TACOMA.—The Standard Chemical Company will commence the erection of new buildings for house machinery, etc., for the manufacture of caustic soda, and flotation oils. The cost of the new plant will be between \$7,000 and \$8,000. The company is chiefly engaged in the manufacture of coal-tar derivatives, disinfectants, etc.

West Virginia

GRAFTON.—The Hazel-Atlas plant, which manufactures glass, is growing rapidly. The original plant is now practically completed. The plant is turning out about four cars of finished product per week. The company expects to commence the erection of a second tank on the original site in the near future. With the second tank running and if the gas department is successful in supplying the required amount of fuel, the company looks forward to putting in another plant of exactly the same type at the east side of their property.

WHEELING.—American Bottle Company, subsidiary of the Owens Bottle Machine Company, 30 East Rand Street, South Chicago, will erect \$2,000,000 plant here for the manufacture of glass bottles.

WHEELING.—The Whitaker-Glessner Company of Wheeling will erect a large sheet mill on its Beech Bottom property. The plant will consist of eight hot mills and is expected to be ready by August.

Wisconsin

STEVENS POINT.—The Whiting-Plover Paper Company will make improvements costing \$100,000 during the coming year. A new mill costing \$50,000 and two new water wheels will be the most important items.

Canada

CHATHAM, ONT.—In the Calgary field the Calgary Petroleum Products Company has installed a small experimental refining plant at its wells near Okotoks. The company is preparing plans for a larger plant. In the Tilbury gas field the Union Natural Gas Company has finished a gasser on the Chris Armstrong farm near Glenwood.

The Imperial Oil Company, which constructed several new stills at its Sarnia refinery, is stated to be planning other large extensions in 1917. The Perfection Stove Company and allied concerns has recently constructed a large addition to its factory.

Manufacturers' Notes

FERROCHROMIUM NOW MADE ON PACIFIC COAST.—The first fifty-ton carload of ferrochrome produced on the Pacific Coast was shipped East on Jan. 15 by the Noble Electric Steel Company. The Noble Company is doing a large business at present.

PAPER EXPORTS DOUBLED.—Exports of paper and paper manufactures this year

will reach \$40,000,000, doubling those of any previous year, according to figures assembled by the Bureau of Foreign and Domestic Commerce.

News print paper exports this year have reached a total value of \$3,430,000 against \$2,260,000 last year, about half of it going to Latin-America. It would seem that there are other countries besides Europe, Asia and high cost of raw materials for our high paper prices.

AMERICAN FIRM GETS BIG ARGENTINE CONTRACT.—The second largest contract ever awarded by the Obras Sanitarias de la Nación, of Buenos Aires, Argentina, was obtained recently by an American firm. The United States Cast Iron Pipe & Foundry Company will supply 60,000 tons of pipe, amounting to about \$3,500,000. The American commercial attaché at London, England, was of assistance in bringing this contract to the United States. A report on the subject has been received from Secretary L. B. Clark, in charge of office of commercial attaché, Buenos Aires.

BRITISH EXPORT PROHIBITIONS.—By an Order in Council dated December 12, according to the "Chemical Trade Journal & Chemical Engineer," manganese, peroxide of, and mixtures and preparations thereof; thorium and its alloys; and zirconium, and its compounds and alloys, are added to the list of goods the exportation of which from the United Kingdom is prohibited to all destinations. Lead (except pig lead), alloys of lead, solder containing lead, and manufactures of lead, or its alloys, not otherwise prohibited; oil varnishes; zirconium minerals; and fish bones are prohibited from exportation to all destinations abroad other than British Possessions and Protectorates. Lead, not otherwise prohibited; iridium, osmium, palladium, rhodium, and ruthenium compounds; white lead; oxalates, not otherwise prohibited; sodium, potassium, and thiosulphates, metallic, not otherwise prohibited; animal hoofs and other glue stock; glue, osseine and concentrated glue, size, fish glue, isinglass, finings and other kinds of gelatine; iridium, osmium, palladium, rhodium, ruthenium, and alloys of these metals are prohibited from exportation to all foreign countries in Europe and in the Mediterranean Sea, and elsewhere other than France, Russia, (except through Baltic ports), Italy, Spain, and Portugal.

The following headings scheduled in previous Orders are deleted: Manganese peroxide, prohibited from exportation to all destinations; and lead, pipe, scrap, or sheet, and solder containing lead, prohibited to all destinations abroad other than British Possessions and Protectorates.

LARGE ORDER FOR CHLOROBENZOL.—The Federal Dyestuff & Chemical Company, Kingsport, Tenn., is reported to have received an order for 3,000,000 pounds of chlorobenzol, and will be executed by the company's new plant at Kingsport.

The goods are for export, and it is expected that the order can be executed within the next six months, with the capacity increased and rapidly increasing capacity of the plant.

Chlorobenzol is an "intermediate" used in the manufacture of dyes, and the Kingsport plant is now equipped to turn it out in large quantities. The demand for this chemical is heavy, and the price is far above normal.

EXPORTS FROM GERMANY TO UNITED STATES FOR 1916.—The total value of the exports invoiced at the American consulates in Germany for the United States during 1916 was \$3,361,900, against \$39,967,183 for 1915. Exports to the Philippines were valued at \$21,428 against \$140,871. No exports were declared during the year for Hawaii or Porto Rico, while in 1915 the shipments were valued at \$89,159 and \$16,841, respectively. Returned American goods were valued at \$2,400, against \$178,546 for 1915.

CONDITIONS IN SWISS DYESTUFF INDUSTRY.—The Swiss dyestuff industry has had to cope, according to Chemical Reports with great difficulties in connection with labor and materials. There are no coke ovens in Switzerland, and the coal-tar products and procuring them have been those which could be spared by belligerent countries, chiefly England. There is only one sulphuric acid works for the dyestuff factories, nitrites, nitric acid, caustic soda, and chlorine are plentiful.

The Swiss dyestuff factories have had to supply the requirements of the home consumers, who formerly dealt almost entirely with Germany, and who are now busy with foreign orders; nevertheless a

considerable quantity has been exported under government supervision in return for raw materials allowed to come in. The price of aniline oil has risen to ten times the normal.

The Swiss silk-dyeing industry is suffering through scarcity of vegetable dyestuffs, particularly logwood. Stocks are nearly exhausted.

ADDITIONS TO BRITISH CONTRABAND LIST.—A proclamation of December 29, 1916, supplements the following as additional absolute contraband:

Oxalic acid and oxalates, formic acid and formates, phenates, metallic sulphites and thiosulphates, soda, lime and black-china powder, platinum, osmium, ruthenium, rhodium, palladium, iridium, and alloys and compounds of these metals, strontium salts and compounds thereof, barium sulphate (barites), bone black. Schedule I, proclamation of October 14, 1915, is amended as follows: For item 8, "ethyl alcohol, methyl alcohol," substitute "alcohols, including fusel oil, wood spirit and their derivatives and preparations"; for item 35, "aluminum, alumina, and salts of aluminum," substitute "aluminum and its alloys, alumina, and salts of aluminum"; for item 36, "wolframite, scheelite," substitute "tungsten ores"; schedule II, for item 5, "fuel other than mineral oils," substitute "fuel, including charcoal, other than mineral oils."

DUST COLLECTING COMPANIES RE-ORGANIZING.—The Clark Dust Collecting Company, Chicago, Ill., announces that it has severed its connections with the Simon, Buhler & Baumann Co., Inc., New York, a Western enterprise, and that they have consolidated with the American Dust Collecting Company to build a full line of dust collecting apparatus, including the American suction filter.

RENNERFELT FURNACES IN THE UNITED STATES.—The following Rennerfelt furnaces are in operation or building in the iron and steel industry in the United States:

Crucible Steel Company of America, Crescent Works, Pittsburgh, Pa. Capacity, 750 lbs., 100 kw. steel steel.

Charleston Steel Company, Charleston, W. Va., 6-ton, 1200 kw. special steel ingots.

Two furnaces, American Foundry & Machine Company, Salt Lake City, Utah, 3-ton, 625 kw. steel castings.

Edgitt Steel & Iron Works, Sedro-Woolley, Wash., 1-ton, 200 kw. steel castings.

Parsons Company, Newton, Iowa, 1-ton, 200 kw. steel castings.

The Samson Iron Works, Stockton, Cal., 1-ton, 300 kw. steel castings.

Ducas & Company, New York City, 3-ton, 750 kw. steel ingots.

J. Leslie & Co., St. Louis, 200 kw. tool steel, Philadelphia, Pa.

Maynard Steel Castings Co., Milwaukee, Wis., 1-ton, 300 kw. steel castings.

New company in Minnesota, not at liberty yet to mention name, 3-ton, 600 kw. steel castings.

Pacific Foundry Company, San Francisco, Cal., 750-lb., 100 kw. special iron castings.

New company, but not at liberty to mention name, 1-ton, 300 kw. steel castings.

Besides this there are two Rennerfelt furnaces of 300 lbs. capacity in the pipe and brass industry, and one of this size for refining ferro-tungsten, another one for melting special aluminum alloys, besides ten special furnaces for making low carbon ferrotungsten.

SULPHURIC ACID IN 1916.—The production of sulphuric acid in the United States in 1916 was much greater than in 1915. The estimate is stated in the Geological Survey of sulphuric acid of strengths of 50°, 60°, and 66° in 1916, expressed in terms of 50° acid, is 4,475,000 tons, an increase of 600,000 tons, or more than 15 per cent. The increase was distributed about equally between acids of strengths of 50° to 60°, and acids of 60° to 66° increase in the production of acid of strength of 66°.

The most notable feature in the sulphuric acid industry was the enormous increase in the production of acids of strengths greater than 66°. The estimate shows a production of these stronger acids of over a million tons as against a production of less than 200,000 tons in 1915. It is not feasible to express the amount of these higher acids in terms of 50° acid; therefore the total given for them is in addition to the total given for acids of strengths of 66° or less.

The estimated output of acids of strengths of 60° and 66° includes by-product acid produced in copper and zinc smelters. The output of acid so produced in 1916, expressed as 60° acid, amounted

to nearly 950,000 tons, or practically the same as in 1915. However, over 110,000 tons of acid of higher strengths was produced at these smelters, a quantity nearly double the product of 1915.

The market conditions throughout the country are reported to have been on the whole better than in 1915, and the value of the product will probably be somewhat higher than it was even during that year.

MANGANESE IN 1916.—Preliminary estimates by D. S. Hewitt, of the United States Geological Survey, Department of the Interior, show that the production of manganese ore in 1916 was about 27,000 tons, the greatest since 1891, when it was 3,000 tons.

The estimate does not include manganeseiferous iron ores that contain less than 40 per cent of manganese, but it is very probable that the production of ores of this class also was much greater than in 1915. This output has come largely from seven states, and the order in production will probably prove to be as follows: California, Arizona, Georgia, Virginia, Colorado, Utah, Colorado.

This order is interesting, because this is the first year in which a western State remote from the steel-producing centers has contributed the largest amount of manganese ore.

The activity among manganese mines in California is due largely to the market for ores provided by the Noble Electric Steel Company. It is not yet possible to state the production of high-grade ores adapted for use in dry batteries, but reports indicate that it will exceed 2,500 tons, and therefore five times that in 1915.

There are now produced in Arizona, California, Utah, Colorado, and Virginia, but the amount produced is still scarcely one-tenth the normal demand.

Prices for manganese ore have been adapted to the manufacture of ferro-manganese rose from a maximum of \$22.50 for 50 per cent ore in 1915 to \$32.50 in March, 1916, except for fluctuations which depended on temporary variations in demand, prices were nearly constant until the last month of the year, when sales at prices as high as \$39 for 50 per cent ore were reported.

There were rumors that a contract for the delivery of 200,000 tons of Brazilian ore during 1917 was placed at \$23 per ton f. o. b. Brazilian ports, from which the freight rate to the interior is \$18 a ton.

Ore adapted to the manufacture of dry batteries (containing 80 per cent of manganese dioxide and less than 1 per cent of iron) continues to sell for about \$55 a ton.

Imports of Manganese ore for the first ten months of 1916 amounted to 495,299 tons, of which 401,177 tons came from Brazil.

For the same period of 1915, Brazil supplied 181,258 tons out of the total of 192,286 tons. There is a prospect, therefore, that the imports for the entire year will prove to have been almost double.

Considering the small part of the demand that was supplied by Brazil during the eight years prior to 1914, it is reassuring to know that the deposits of this country can be made to yield such enormous quantities of ore. Imports from India, Cuba, Panama, and Japan were also greater than in 1915.

Imports of ferro-manganese for the first eleven months of 1916 were 73,425 tons, which is nearly 50 per cent more than for the corresponding period in 1915, though bearing a smaller ratio to the domestic production. Prices reached the highest figures ever recorded in the United States in April, 1916, when, it is reported, \$400 a ton was paid for a small lot for immediate delivery.

For the period of 1915, the price of this product declined steadily to \$160 a ton in October, then rose to \$175 again in December. The price of spiegeleisen carrying 20 per cent of manganese ranged from a maximum of \$52 in July to \$40 in December.

An important consequence of the prevailing high prices of manganese alloys is the attempt on the part of steel makers to use ferro-silicon. The extent to which substitutes for manganese in steel may be used has not been determined, but experiments by several steel works show that an alloy of iron, carbon, and uranium may be satisfactorily used to replace a part of the ferro-manganese commonly added.

Although a number of mines in Virginia, Colorado, and Arizona were reopened during 1916, the greatest activity is reported among mines in California, Arizona, Utah, New Mexico, and other western States.

This is due in part to the operation of the steel reduction plants in California and Washington, but more largely to the low percentage of iron in some of the western ores.

Few eastern mines that operate on small deposits can afford to produce in large quantities ore that contains less than 1 per cent of iron, and therefore most of

the eastern mines ship their product to eastern furnaces to be reduced to ferro-manganese. The inaccessibility of most western deposits makes it unprofitable to ship ore to eastern makers of ferro-manganese, even at the high prices they are now offering for manganese ore. On the other hand, many western deposits are known and more have been discovered during recent years, which are capable of producing manganese with less than 1 per cent of iron. At prevailing prices for such ores, they may be profitably shipped as far east as New York. There is a prospect that several western mines may be present to ship high-grade ores to eastern markets even when prices recede to the level of years prior to 1914.

ITALIAN FIRM WANTS CATALOGS.—The firm of Bonaparte & Salvini, 76 Foro Bonaparte, Milano, Italy, is desirous of receiving catalogs, prices and conditions of sale from American manufacturers of electrical apparatus and other industrial material.

BONUS FOR CUTLER-HAMMER EMPLOYEES.—The shop employees of the Cutler-Hammer Manufacturing Company of Milwaukee, all received a Christmas bonus on or about the 23rd of December, and before New Year's Day a notice was posted which advised everyone of a bonus of 10 per cent of the year's earnings or salary. This bonus went to all of the 2,400 employees of this company.

MOULTON ENGINEERING COMPANY OPENS NEW YORK OFFICE.—The Moulton Engineering Corporation of Portland, Me., announces the opening of a New York office in the Woolworth Building. Mr. Horace W. Flashman, who for a number of years has been connected with the Western Electric & Manufacturing Company, will be in charge of the office.

The company is prepared to render service in general, civil, mechanical, and electrical engineering, and in the development of special process. The company is also associated with the Electron Chemical Company, manufacturers of the Allen-Moore electrolytic cell.

Manufacturers' Catalogs

ESTERLINE COMPANY, Indianapolis, Ind. Esterline graphic efficiency instruments model E. B. catalog No. 369. Clocks, ammeters, voltmeters, wattmeters, speed recorders.

KIESELGUHR COMPANY OF AMERICA, 11 Broadway, New York City, S. I. Co. Cell products for heat insulation, boiler settings, hot air stoves, flues, furnaces, kilns, ovens, etc.

MESTA MACHINE COMPANY, Pittsburgh, Pa. Mesta improved pickling machines. Patented. Used in chemical and fertilizer plants and a large number of miscellaneous metal products.

SPRAY ENGINEERING COMPANY, Boston, Mass. Spraco evaporators for washing and cooling of steam turbine air for steam-turbine driven generators.

The Niagara Falls Power Famine

A un point de vue plus objectif il est bien évident que cette
crise de la houille blanche à Niagara Falls est l'indice que
les Etats-Unis sont beaucoup plus pauvres qu'on ne se
l'imagine en forces hydrauliques. Et il ne faudra pas perdre
de vue plus tard cette indication quand on étudiera l'orienta-
tion de certaines fabrications électrochimiques.

Thus the *Journal du Four Electrique* in its issue of
Jan. 1, 1917, and we would respectfully submit the re-
mark to the distinguished consideration of the eminent
gentlemen in Washington who will be so largely respon-
sible for the future of electrochemistry in the United
States.

At this writing the Cline bill has passed its third read-
ing and the permanent legislation in regard to Niagara
power which it proposes includes, of course, the inevit-
able tax on the water used. Equally inevitable appears
the fate of the bill when it goes to the Senate, which will
refuse consent to the tax. This means amendment fol-
lowed by conference and then nothing will be done.

Meanwhile, with the nation facing the probability of
war, munition plants and all kinds of industries, abso-
lutely necessary to a country at war, dependent on the
products of the Niagara Falls electrochemical industries,
must suffer because the eminent gentlemen in Washing-
ton know the value of the monopoly scare as a vote
catcher.

The temporary relief measure passed by Congress is
not of the very smallest benefit to the United States. In
the first place, ice is not a satisfactory source of power.
and at the present time weather conditions are such that
the additional water is in this unavailable form. Sec-
ondly, when the weather improves conditions will be far
worse than before owing to Canadian demands. Canada
knows what war means and hence the demand for 50,000
hp. by April 1st will be insisted on and will be obtained
by the simple process of cutting off this amount of power
from the United States. Finally, unless some unfore-
seen event changes present Canadian developments no
power whatever will be exported from Canada to the
United States by the end of this year.

Let us consider what this means. According to for-
mer legislation 160,000 hp. could be exported from Can-
ada to the United States. Our electrochemical indus-
tries counting on this import and the normal improve-
ments in the efficiency of hydro-electric developments
have built their great plants and made themselves a vital
necessity to the whole country. Now in the time of our
need we have a power famine which in a few months
will be infinitely more serious than at present. Of the
160,000 hp. formerly available not a mouse-power will
come from Canada.

The additional 4400 cu. ft. ought to give us 80,000 hp.

if developed at high efficiency and the water now used would give an enormously increased power were it used in the efficient manner made possible by the modern improvements in hydro-electrical engineering. None of this, however, is possible so long as the inexpert bungling of legislators prevents the necessary developments. As far back as 1906 when the infamous Burton Act was passed the Niagara Falls Power Company had all its plans completed for finishing its great pioneer work begun in the last decade of the nineteenth century. Had it not been for that Act, Niagara Falls would long ago have had from this development 200,000 hp. in a plant showing the highest attainable efficiency. Even had some common sense penetrated the legislative mind in 1909 when the Burton Act expired, this work would have been undertaken, but the monopoly-scare mongers were busy and all thoughts of efficiency and the conservation of our resources from a strict engineering standpoint as well as from the broader viewpoint of national industry were disregarded.

It cannot be too often or too strongly insisted that we shall never get the full efficiency out of the water taken from the Niagara River until permanent, common-sense legislation warrants the great expense involved in taking advantage of modern hydro-electric engineering principles and methods.

Once more with war threatening us and the country looking to Congress for legislation that will put us in the strongest position to face its strain as well as that of the economic struggle which will follow it, our legislators have an opportunity to retrieve the disastrous blunders of the past, blunders which have caused a power famine daily increasing in intensity and which the whole country will feel before many months are past. Will this opportunity be let slip for the sake of collecting a small revenue or to please the dupes of the monopoly-scare monger? Every cent of a tax of this kind is simply a hindrance to the attainment of the ideal in the efficient use of water power and is surely borne by the electrochemical industries and those dependent on their products. For the purpose of collecting a small revenue the larger indirect revenue to be derived from the industries supplied by the hydro-electric power is sacrificed and the welfare of the whole country injured to an extent that it is impossible to estimate.

Truly the Washington efficiency engineer has a single eye to political conservation.

Tonnage of Iron in Future

It has always been difficult to believe that the rate of growth previously maintained in the American iron and steel industry could be maintained in future. The fact that the growth in tonnage had been in geometric ratio was in itself suggestive that it could not continue in the same fashion. In the years immediately following the panic of October, 1907, it was felt in many quarters that at last the time had arrived for the rule to break down, that indeed it had broken down. The large tonnages lately produced, however, have practically put the rule in operation again. As shown in

these columns Sept. 15, 1916, pig iron production in the decade ended Dec. 31, 1915, compared with output in preceding decades, was very nearly in conformity with the old rule of a doubling every ten years. In 1916 the output was much larger, and 1917 promises a gain, where a comparison made by using the decade ending with the present year will show a still closer conformity.

We can look into the future with clearer vision than one decade or two decades ago, because we have more history to guide us. The increase in the use of steel and iron is no longer mysterious. When mild steel was a new thing a structure made of it was regarded as a permanent work, not altogether like the pyramids, perhaps, or like the iron pillar at Delhi, now nearly if not quite 3000 years old and still "going strong," but at any rate something about which it was reasonable to wonder how long it was capable of lasting. Now we know it is more likely to be a question of how long men will continue to need it. Skeleton steel buildings only ten years old have been torn down to make way for much taller structures with much heavier members.

For the consumption of iron per capita to remain the same it would, of course, be necessary for the population to increase at the same rate as the production. This, of course, it has not done. If the population growth were in geometric ratio it would not be in as great a ratio, and the per capita consumption would have to increase. Population growth, however, has not even been in geometric ratio. It was so, approximately, from 1790 to 1860, the increase per decade being about 35 per cent, but in the three following decades the increase was only about 26 per cent, while the decennial increase from 1890 to 1910 was still smaller, 21 per cent.

The production of pig iron per capita was about 94 lb. in 1870, 330 lb. in 1890, and 670 lb. in 1910, while it is now about 930 lb., taking only the population of continental United States.

It is really a question of the needs and purchasing ability of the people. The wealth of the United States doubles in a little more than a decade. The freight ton-mileage of the country has been doubling about once in every dozen years.

The rapid growth of the automobile industry is often cited as an illustration of the expansion in the use of steel. We beg to use the illustration of the automobile industry just the other way. When people buy 1,500,000 automobiles in a year at, say, \$800 apiece, they are spending nearly a dollar for every pound of iron thereby absorbed, an enormously expensive way to provide an outlet for iron. It is no illustration at all. Rather one should view the case that the people are rich enough so that more than a million new owners a year appear, and soon they will be well provided and part of the money will be spent otherwise.

The laying of petroleum pipe lines, which has consumed more than a million tons of iron and steel, did not noticeably interfere with the growth of rail freight traffic, nor will the automobile. The past few years

have been bad with the railroads, from too much saying by state and federal governments of what they must not do, but soon, there is good reason to hope, will come the time when the government will tell the railroads what they must do by way of expansion to meet and anticipate the needs of the country, and will assist them, if necessary, in the expansion. The advent of the steel freight car and heavier locomotives forced the railroads, ten years and more ago, to relay nearly all their track with heavier rails. Now still heavier cars and locomotives are coming, and when the scruples of the railroads as to the quality of a 125 or 150-lb. rail, as compared with an 85-lb., are removed, another era of rail replacement will come. Then there is electrification, no longer a technical problem, but almost wholly a financial one and commercially this will be perhaps the biggest development of all; and we may add in parenthesis, it may affect the copper industry even more than the steel industry.

There are few uses for steel in which a large expansion in tonnage cannot with confidence be predicted. Most of these lines of consumption, hydroelectric development as a conspicuous instance, are in their infancy as compared with railroading, which promises heavy consumption in future.

It has been suggested that as time passes and the amount of iron and steel in use increases, the amount to be won from the ground by ore mining will not need to increase so rapidly, as more scrap will be returned after use. It is a question of mathematics. If the proportion of the production that will eventually come back, as against that which is totally lost by oxidation and comminution or dispersion or whatever it may be called, remains constant, and the average period of life remains constant, then with a geometric rate of increase in consumption the rate of increase in production will not change. If production doubles each ten years, and one-half comes back as scrap in ten years, then the scrap will always be one-fourth the production. If it is twenty years instead of ten the proportion will always be one-eighth. If the period of employment lengthens, the proportion of scrap to supplement new production will decrease. If the period of employment decreases, the smelting of iron ore will increase by smaller ratios, but the activity in reworking will increase.

On the Blindness of Others—and Ourselves

The other day a woman who ran an army canteen in England last year related how, with the problem often before them to feed several hundred soldiers on absurdly short notice, no labor saving devices were at hand, no dish-washers or bread-cutting or sandwich machines were available; in fact, there was nothing provided to save work.

In John Masefield's book on the ships of Nelson's day it is noted that "eart of hoak and other lumber was seasoned in water and that the British ships were heavy and damp and unwholesome in consequence; yet they would not change their methods. The Yankee clipper ships were built on French models and were far more

speedy and desirable, but nothing could drive into the heads of those British shipbuilders the idea that it is better to season wood than to soak it.

Before these days of blood and anguish a very distinguished American engineer went through the Krupp works at Essen. With great pride they showed him seventeen men at a job successfully accomplishing what it takes three men to do in Pennsylvania, and in another place a military company of marching men were doing the work of a chute.

If we only close our eyes to the inward glance; if we address ourselves to looking very hard at other people and neglect the thought of our own short-comings, it does seem as if those foreigners were dunderheads for fair. This is a habit with us. We may admit that we have single faults but other people are promiscuously and miscellaneously wrong. Ask any Democrat what he thinks of the Republicans and he will say they have no character and no ideals, and the Republican will say of the Democrats that they have no sense. We are right and the other fellows are wrong.

Now we respectfully submit the gospel of modesty. We can give plenty of reasons but we can give no excuse for our beehive coke ovens. We can explain the wretched condition of our army, but that does not excuse it. We can explain how some industries use up men and take the hearts out of them whereby discontent and disorder and hatred and malice are caused to thrive like a green bay tree, but that does not excuse them. We can point with pride to the expedition with which living shacks for workmen have been constructed, but if they are unwholesome or even ugly we should do better to recall the pride, send for a sanitary engineer and get busy.

In the big vision of things explanations do not excuse. The sooner we get this into our heads and hearts the better it will be for us. All the world's a stage—it's a regular exhibition, and all our works are on show. We cannot attach our personal labels to them, however, whether we want to or not, for more than a very little while. Our works are on show as the product of the people of the United States and that is the only label that will stick. The people of the United States have fallen short in many ways, and all of us have had a hand in it.

The whole world is in a very bad way and most of the children of the earth see red and red only. Now Crile and many others have shown the inwardly destructive force of anger, and by this a great part of the world is being crippled in mind as well as in body. We shall have that to meet, and to avoid, if we would keep our heads, no matter how much fighting we may have to do. What we need above all things to-day is the philosophic vision that looks for the right, that sees our own faults and tries to remedy them. It is always bad diplomacy to point out their faults to other peoples. They have to find them out for themselves by reason or by force of circumstance. Talking will do no good. But our own lapses are excellent subjects for us to consider. They are not such pleasant subjects as the faults of others, but they are vastly more wholesome.

Readers' Views and Comments

The Flotation Suit Decision

To the Editor of Metallurgical & Chemical Engineering

Sir:—A very interesting letter signed "A. B. C.," appears in Feb. 1 issue of your journal re the legal status of flotation. One can agree with the digest of the writer and yet not accept his conclusions that the Supreme Court has made any mistake or is likely to change its mind.

All agree that the U. S. Patent Office is not what it was intended to be, and that litigation is of such a nature and expense that the inventor has little chance, and only when large capital undertakes the defense of a patent, as in the flotation cases, can the patent get a fair hearing.

The flotation case is one of the first instances where industry has been checked by the courts, and forced to recognize an invention that it adopted and used in defiance at immense profit.

The argument of "A. B. C." as to the academic knowledge previous to U. S. Patent No. 835,120 was all known and admitted, the commercial use of any of this knowledge was non-existing, yet there was great commercial necessity to find a commercial process. The court practically disposed of all this previous art under the fair assumption, knowing the conditions, that none of it was commercial.

If it was an obvious engineering feat to find a minimum and commercial percentage of oil, it had not been done, and the courts decide it was thus not obvious.

While a mere question of degree is not a patentable thing under our law, where the question of degree develops a large commercial practice, even though the difference in results is hard to define, there is an obvious discovery in the art or large commercial practice would not follow.

It appears a very just decision that there was invention under U. S. Patent No. 835,120, and that some degree of range in practice must be adopted to define infringement. One per cent was given as a convenient gross amount of oil.

If industry has now discovered that more than 1 per cent of oil is equally useful, it is their right to use such degree, but this cannot in any way reflect upon the opinion of the court, because this knowledge was discovered long after, and as a result of long experience with less than 1 per cent of oil, which gave birth to the flotation industry.

As to who was the true inventor of less than 1 per cent of oil is not now at issue, as Patent No. 835,120 has the legal status. The courts found justly that a large commercial practice followed at once the discovery that less than 1 per cent of oil was practical and sustained the patent that described such.

The purpose of the Patent Office is to encourage invention by offering reward to inventors in the form of royalty protection, and thus create advance for the community.

The result has for many years been very disastrous to inventors who are not capitalists and have no time for business practice.

Industry made the discovery that it could employ counsel and cause court delays and so defeat the just reward of invention, and that such practice was more economical than paying royalties. This is in direct defiance of the patent laws which grant a period of

royalty protection, because the refusal to pay royalty discourages invention and delays community advance.

In the end the present practice of industry is a short-sighted one as a community loss is the greatest that can occur.

The flotation decision is a most valuable precedent, and probably establishes the fact that invention that brings commercial practice will be protected, irrespective of academic theory or engineering practice that become obvious after the patent was issued.

How much better it would be for industry to aid the inventor, where they desire to use his invention or supposed invention, and advance him money to test the validity if in question, and thus prevent capitalizing of patents solely for monopolistic purpose.

The practice of attempting to own the inventor or force him to assign at a nominal price, or before there is any established value, should be deplored as a form of piracy.

Invention or research is a vital force that precedes all industry advance, and while radically different in mentality is in our advanced civilization perhaps quite as important. Even though the ownership of the flotation patents is to be deplored, if the lesson is learned by industry to deal with the inventor directly and permit him to hold and administer his inventions, aiding him in so doing, it is cheap even at the price of \$50,000,000 more or less that it may cost industry to settle its bills.

The inventor should profit only by the commercial value and validity of his invention through royalty. Industry should be glad to pay royalty in commercial degree as community progress, and profit solely by manufacturing and salesmanship.

There should be no such thing as control of common commodity patents by industry.

The interpretation of the law by the courts is practically always an echo of public opinion of the same kind, and "A. B. C." will do well to look a little beyond the argument he presents.

METALLURGICAL ENGINEER.

Electrolytic Oxidation of Sulfurous Acid

To the Editor of Metallurgical & Chemical Engineering

Sir:—I was much interested in the article by Messrs. M. De Kay Thompson and N. J. Thompson on "The Electrolytic Oxidation of Sulfurous Acid," page 677 of your issue of Dec. 15, 1916. This subject has been of no small importance in the field of copper leaching investigation where the copper is obtained by the electrolysis of a sulfate solution and the possibilities of making acid and lowering cell voltage by the utilization of such an anode reaction become worthy of attention. Of course, the same subject is intimately connected with several important lines other than copper leaching.

It would be interesting if Messrs. Thompson would give us figures and a discussion on the possible application of their data to a commercial cell. In the latter case, of course, the anode would not be platinum and the reaction could not be so perfect, but an idea would be obtained of the maximum amount of sulfur dioxide per commercial unit that could be possibly oxidized under given conditions.

Multiplying current density by current efficiency by the factor 1.192 (which is the grams sulfur dioxide

oxidized per ampere-hour when this is the sole reaction) gives at once the weight in grams of sulfur dioxide completely oxidized to sulfuric acid per square decimeter of anode surface per hour, for any given experiment. The resulting figure is a measure of the absorption yield of sulfur dioxide or the production yield of sulfuric acid or the relative velocity of the desired anode reaction, according to the view-point. It could be applied at once to any commercial cell unit of given size. The shape of the curve would evidently be the same as that of the current efficiency curves as given by Messrs. Thompson.

The current efficiencies obtained in the investigation seem remarkably good. Under such conditions the depolarizing effect would seem to be at its maximum and indeed in the case of 10 per cent sulfuric acid no anode oxygen was evolved at all even with very considerable current densities. At first glance, it might seem that the anomalous condition prevailed of perfect absorption with no depolarizing effect, as the cell voltage was 4.00 for 10 per cent sulfuric acid and a current density of 19 amperes per square decimeter (the presence of the porous cup diaphragm and the extra resistance thereby introduced into the circuit is kept in mind). However, 19 amperes per square decimeter is 176 amperes per square foot, an extremely high density when compared with metal deposition practice, where current densities commonly range between 10 and 40 amperes per square foot. Any depolarizing effect is therefore masked by the high electrolytic resistance drop and Messrs. Thompson's figures on cell voltage can hardly be discussed without further information from them. Comment on any depolarization observed and on this phase of the subject in general would be extremely interesting.

Apropos of a sulfur dioxide anode, several years ago the writer directed an investigation of a sulfur dioxide-platinum black anode immersed in a solution of copper sulfate, sulfurous and sulfuric acids. On open circuit the single potential was found to be $+0.42$ volts (electrode positive to the solution; here as elsewhere the sign refers to the charge on the electrode). A normal calomel electrode assumed to be $+0.56$ volts was used in making the measurements. A copper cathode in the same solution had a single potential of $+0.54$. The open circuit combined cell voltage was therefore only $0.54 - 0.42$, or 0.12 volts, a figure that looked extremely promising.

Sad to relate, on applying something like a commercial current density to the cell, about 30 amperes per square foot at the anode and 15 at the cathode, the sulfur dioxide electrode "broke down" completely, even changing its sign, becoming -1.10 volts. The copper cathode went to $+0.70$, so that the cell voltage at the electrodes was $1.10 + 0.70$, or 1.80 volts. The electrodes were spaced 1.5 in. between surfaces and with the strength of solution used the total electrolytic resistance drop amounted to 0.55 volts. The external cell voltage under running conditions was therefore $1.80 + 0.55$, or 2.35 volts total, instead of the approximately 0.7 volts that we had hoped for. Some sulfurous acid was oxidized to sulfuric but the reaction seemed too slow to appreciably depolarize the cell or to promise any practical advantages. That using still higher current densities might have caused any improvement in the matter did not occur to anyone at the time and the investigation was therefore dropped as leading to negative results. It was made with some care and using delicate instruments, but not under exactly research conditions or using pure materials.

The writer has ever after been somewhat skeptical of the commercial utility of using sulfur dioxide as an anode depolarizer when electrolyzing copper sulfate solu-

tions with insoluble anodes. However, some very broad claims have been made in the past, even down to running cells with no more energy consumption than in the case of soluble anodes. Of course catalytic agents in the solution, iron, etc., have a large effect on the oxidation of sulfur dioxide at the anode and would help to give the result desired. Still, it would be interesting to learn of a single running plant at the present time where depolarization with sulfur dioxide is being satisfactorily used on a commercial scale.

MAURICE R. THOMPSON.

General Electric Co.,
Power and Mining Department,
Schenectady, N. Y.

* * *

To the Editor of Metallurgical & Chemical Engineering

SIR:—Replying to Mr. M. R. Thompson's comments on the article by Mr. N. J. Thompson and myself, I would say that the high voltage found necessary to get the currents desired was due partly to the diaphragm and to the polarization of the hydrogen liberated. On account of lack of time, no single potential measurements of the anode were made. These, of course, are important and it is hoped to add them later. It would appear from the measurements of your correspondent that there is a resistance to the oxidation of sulfurous acid similar to that observed by Haber and Russ in the case of hydroquinone (*Z. f. phys. Chem.* 47, 257, 1904).

M. DEKAY THOMPSON.

Cambridge, Mass.

More Publicity Urged on Industrial Research Laboratories

To the Editor of Metallurgical & Chemical Engineering

SIR:—The undersigned Committee on Engineering of the General Committee on Research of the American Association for the Advancement of Science feels that it is timely to issue the following appeal to the industrial research laboratories of the country.

In the course of work done in the numerous industrial laboratories of America, many physical and commercial constants and data of great scientific interest and value are doubtless arrived at, and which may, for a certain period of time, constitute an asset of considerable commercial value to the particular corporations in question. During this period, everyone recognizes the proprietary right of the industrial laboratories to the retention of this information.

A time frequently arrives, however, when such scientific information loses its commercial value (often by being duplicated in other laboratories), and just at this point we wish to impress upon the industries their obligation to enrich scientific literature with such facts and data, which might otherwise be lost or forgotten.

Some of our industries have been reproached with the suspicion of acting as sponges, in that they absorb an immense amount of useful information from scientific literature without giving any return in kind. This suspicion would be entirely removed if, from time to time, scientific information which has ceased to be of commercial value were contributed by them to its appropriate channel and thus became available to all scientific workers throughout the world.

If any doubt exists as to the appropriate channel for the publication of such scientific data and communications, the secretary of the A. A. S., Dr. J. McKeen Cattell, Garrison-on-Hudson, New York, will be glad to act as intermediary and to forward such communications to the proper scientific body.

A. E. KENNELLY, J. W. RICHARDS, A. SAUVEUR, A. N. TALBOT, C. C. THOMAS.

Who ?

From the "Transactions" of the Buffalo Section, Institute of Literary Engineers.

Who takes the pleasure out of life and makes existence Hell?

Who fires a real good-looking one because she cannot spell?

Who substitutes a dictaphone for coral-tinted ear?

The penny-chasing, dollar-wasting efficiency engineer!

Coming Meetings and Events

American Institute of Mining Engineers, annual meeting, New York, Feb. 19-22, 1917.

American Chemical Society, New York Section, Nichols Medal Award, Chemists' Club, New York, March 9, 1917.

American Chemical Society, spring meeting, Kansas City, Mo., week of April 9, 1917.

American Electrochemical Society, spring meeting, Detroit, Mich., May 2-5, 1917.

American Electrochemical Society, autumn meeting, Pittsburgh, Oct. 3-6, 1917.

National Safety Council Broadening Its Activities

The National Safety Council, the leading accident prevention agency in the country, is broadening its activities, and has commenced monthly publication of a series of safe practices leaflets. The council has a committee of fifty safety experts working out the maximum and minimum requirements in safeguarding, and has already issued three leaflets on this important work. These are entitled respectively "Ladders," "Stairs and Stairways" and "Boiler Rooms." Others will be issued monthly.

The purpose and scope of these leaflets is explained in a preliminary announcement in the leaflet on "Ladders" as follows:

"The National Safety Council was established to help free mankind from accidents, and, to that end, to gather to itself as members all those concerned and interested in the safety movement, and to bring about an understanding of accident causes and find and apply remedial measures.

"The field has been new and the various services rendered have met the need, in so far as the council's modest income from its nominal fees, its experience and the experience of its members have permitted. The time has now come when the pioneering period has partially passed and our accumulated experiences permit, and the awakening needs require, that the great amount of collected and obtainable safety information be put into concrete and popular form for the benefit of the cause.

"The executive committee has, therefore, decided to compile the best information obtainable about safe practices of all kinds and to present same in a logical and orderly form. It is hoped it will become an encyclopedia of information on all phases of the subject. It is fully realized that this is a very large undertaking, but this need not deter us if the accomplishment is necessary to the progress of the council's purpose and its service to its members. The council will simply do the best it can with such a large and important subject, relying upon the co-operation of the members for the success of the plan.

"The gathering and compiling of data will have to be sectionalized to cover the field."

The organization includes in its membership many of the leading industrial concerns of the country, and

has offices in the Continental & Commercial Bank Building, Chicago. Mr. W. H. Cameron is general manager.

Award of the Elliott Cresson Medal to E. F. Northrup

The Franklin Institute has recently awarded its Elliott Cresson Gold Medal to Edwin Fitch Northrup, Ph.D., research physicist, of Princeton, N. J.

This award was made in recognition of a special type of electric furnace developed by Dr. Northrup, in which a temperature of more than 3000 deg. C. can be developed, and of his pyrometric methods and new pyrometric apparatus for the direct and accurate reading of high temperatures up to 1600 or 1700 deg. C. Means are provided whereby, with a slight modification in the pyrometric apparatus, rapid measurements can be made of the resistivities of many molten metals and other liquid materials through a wide range of temperature.

The Western Metallurgical Field Shale Oil

Experimental Plant for the Extraction of Oil from Shale for Flotation.—After a lengthy and careful investigation as to the suitability of oils extracted from Colorado shale for flotation, the Oil Shale Mining Company of Colorado has decided to install an experimental plant for the extraction of the oil near De Beque, Mesa County, Colorado. Endeavors are being

FIG. 1—RETORTS USED IN THE DISTILLATION OF OIL FROM SHALE

made to have the necessary apparatus ready for shipment by the beginning of March.

The initial plant unit will consist of six retorts, similar to the Henderson type, in successful use in Scotland, where the shale oil industry has been in operation for more than fifty years. The retorts are made of cast iron and are 16 ft. in height, tapering from 20 in. at the bottom to 16 in. at the top. At the bottom of each retort is a grate, through which the cinders are removed to a discharge. Near the upper end of each retort is an exhaust, connected with a low vacuum pump, which draws off the volatile vapors which are to be condensed. The retorts are charged from the top through hoppers, which are kept closed during operations. The heating is done from the outside. A grate at the bottom of the chambers surrounding the retorts supports the fuel bed. The products of combustion impart their heat to the retorts and the charge, and then go to the stack. The heating chamber is made of common brick lined on the inside with a layer of firebrick. The retorts are placed in two rows of three each. Fig. 1 shows a vertical section through the apparatus.

The shale, suitably crushed, is fed through the hoppers into the retorts and subjected to distillation under diminished pressure. The vapors are withdrawn through the exhaust near the top of the retort, and are condensed by passing through a metal coil immersed in cold water. No efforts are being made at the present time to fractionate the oil, as the demand of the product for flotation processes is such that the company is looking toward the money made by these sales to defray the expenses of any further experimental work.

It is claimed that the oil thus obtained is a good frothing agent, and does not become as viscid as coal-tar oils when used in connection with cool water under identical conditions. It is estimated that the unit as constructed will yield 20 bbl. of oil per day at 42 gal. to the barrel. The market value per barrel will range from \$4.50 to \$6. A ready market for the output is claimed by the company.

Company Reports

Annual Report of The Granby Consolidated Mining, Smelting and Power Company, Ltd., Ending June 30, 1916.—During the fiscal year the production of the various plants connected with the company from 1,897,251 tons of ore treated was 42,198,083 lb. of copper, 487,845 oz. of silver and 44,848 oz. of gold. At the Anxox Smelter, Anxox, B. C., three furnaces were operated on green ore, while a fourth was used for regrading matte. The tons of ore per furnace day increased from 630 to 692 and the tons of charge from 846 to 929. The cost of smelting and converting was \$1,804 per ton of ore, or \$0.073 less than for the previous year. The amount of ore treated at this plant was 822,919 tons, yielding 29,562,177 lb. of copper. The Anaconda charging system was installed during the course of the year, and the shaft depth of No. 4 furnace was increased by 5 ft. for experimental purposes. The latter change proved so satisfactory that any new furnaces will be built on the same type.

The Grand Forks Smelter handles approximately 500,000 tons of low-grade copper material high in silica. Eight furnaces were in blast. Up to the present time this material was not taken in the ore reserves, but on account of the high price of copper which prevailed during the past year the handling of this material became profitable. For the first six months of the year the cost of smelting and converting was \$1,233 per ton. The plant also converted 21,428 tons of matte from the Anxox smelter.

Philadelphia Hearing in Miami Flotation Suit Before Court of Appeals

The hearing of the Minerals Separation vs. Miami Copper Company infringement suit commenced before the United States Court of Appeals for the Third Circuit in Philadelphia on Tuesday, Jan. 30, and continued until the following Saturday noon.

In the lower court, the United States District Court for the District of Delaware, Judge Bradford had rendered the opinion that the principal patent, 835,120, for a fraction of 1 per cent of oil in its principal claims, was valid and infringed; also that the patent 962,678, for soluble frothing agents was, in the claims under consideration, valid and infringed, but that the third patent in suit, 1,099,699, for aromatic hydroxyl frothing agents without acid and in the cold, was invalid (*Met. & Chem. Eng'g.*, Oct. 15, 1916, Vol. XV., pages 433 and 441).

The appeal was therefore a cross appeal; the Minerals Separation appealed from Judge Bradford's finding as to the third patent in suit, while the defendant in the lower court, the Miami Copper Company, appealed on the other hand as to the findings on the first and second patents in suit.

Judge Bradford in his opinion had stated that the reduction of oil in patent 835,120 was so great as compared with the amount of oil used in prior-art processes as in itself to constitute invention—that is, that the reduction of oil *per se* was patentable. This was at variance with the law finding of the Court of Appeals in San Francisco which had maintained in the Hyde case that the mere reduction of oil was not patentable and had found upon matters of fact that there being only a difference of oil, patent 835,120, was invalid.

In the Supreme Court of the United States the patent 835,120 was found to be valid, this decision following Judge Bradford's by only a few weeks.

This condition then left the case before the Circuit Court of Appeals in the Third Circuit (the Miami case) with two main contentions.

There was a difference of opinion as to what the interpretation of the Supreme Court decision really should be.

The Miami attorneys claimed that the Supreme Court had in its decision affirming the validity of the patent definitely limited the patent to a fraction of 1 per cent of "oil" in combination with a novel agitation, greater than previously used, by "beating in" air, and with the formation of a characteristic "froth," different from any heretofore produced.

Under this construction the decision of the United States Supreme Court was at variance with that of Judge Bradford and in harmony with the Court of Appeals of the Ninth Circuit, as to law, but at variance with the Ninth Circuit as to fact.

The pith of the question before the court as to infringement or otherwise therefore, was largely dependent upon the manner of interpretation of the Supreme Court decision in the Hyde case. In the discussion and for illumination of this, various prior-art processes were considered and experiments shown.

Preliminary to the arguments the court requested each side to present "a skeleton" of their respective cases, so that the court might then more understandingly follow the arguments.

After this each claim was taken up separately and the Miami attorneys stated what part of each claim they acknowledged as used in the operation of their process and what part they denied. For example, "ore pulp"—"admitted"; "small quantity of oil, fraction of 1 per cent"—"admitted"; "agitation to produce a froth"—

"denied"; "and remove the froth"—"denied," etc. Thus through each claim was analyzed.

The judges sitting were Judges Buffington, MacPherson and Wolley. The argument on behalf of Minerals Separation was made by Mr. Henry D. Williams and the closing by Mr. Wm. H. Kenyon; for the Miami Copper Company the argument was made by Mr. Louis Marshall and Mr. W. A. Scott, and the closing by Judge George Gray of Wilmington, Del. The latter had previously sat upon the very bench he was addressing, and with two of the judges now on the bench, Judges Buffington and MacPherson.

As in the court demonstrations in Wilmington, illustrative of the prior art, there was a wide discrepancy as to the interpretation of the disclosures. (See *Metallurgical and Chemical Engineering*, July, 1915, Vol. XIII, page 409.)

There was also an important difference in this court in the experimental illustration of the Miami Copper Company's process.

The Minerals Separation experts agitating the pulp violently in "Gabbetts," which they stated represented a centrifugal pump and Pachuca tank in the Miami initial plant, whereas the Miami experts very gently mixed the pulp and oil and then introduced to the canvass-bottom cell and the spiral coil apparatus of prior patent 793,808, which process Judge Bradford had stated in his decision was the process of the Miami Copper Company. The Minerals Separation experts obtained their air for the cell from compressed-air cylinders at 200 or 300-lb. pressure, admitted to the cell through reducing-pressure valves, which psychologically at least impressed the court with the idea that the air was "shot into" the pulp—an impression which seemed to be dispelled when the court witnessed the Miami company's experimental illustration of their process.

Judge Gray made the closing argument for the Miami company. He dwelt upon the limiting conditions imposed by the United States Supreme Court as to novel violence of agitation and characteristic permanence of froth, contending that to broaden the patent 835,120, so as to cover the operations of the Miami Copper Company's process would in effect be to reincorporate the original claim 12, which the U. S. Patent Office had denied, and which patentees had withdrawn, a claim in which the terms "agitate to produce a froth" had not been used.

Mr. Kenyon made the closing argument for the Minerals Separation, contending that the apparent limiting clauses in the Supreme Court's decision were part of the description, not of the decree, and that the "short step" referred to was the step "turning failure into success," and that the patent was, therefore, in effect "a master patent" if not actually the pioneer patent.

Chemical and Electrical Porcelain

The "Chemical and Electrical Porcelain" meeting held jointly by the New York Section of the American Electrochemical Society, American Chemical Society and Society of Chemical Industry on Friday evening, Feb. 9, was very well attended and the papers were very interesting. Dr. COLIN G. FINK presided as chairman of the New York Section of the American Electrochemical Society which had made the arrangements for the meeting. The international situation has made us dependent on domestic sources for porcelain and, as in many other lines, the manufacture of this commodity is commanding a great deal of attention. This is especially true for chemical porcelain for which we were formerly dependent on foreign sources of supply.

Dr. CHARLES F. BINNS, of Alfred, N. Y., director of the New York State School of Clay Working and Ceramics, at Alfred, gave an interesting illustrated talk on the history, constitution and manufacture of porcelain, showing some microphotographs which brought out many interesting points. The various furnaces and other apparatus used were also described. Dr. Binns has devoted a life-time to the subject of ceramics and did not think the volume of American business in chemical porcelain would warrant a separate factory for its manufacture, although we have the raw materials and everything necessary for its manufacture, if the proper technique is observed. He also thought that protection was necessary to protect the industry from foreign competition after the war.

Mr. L. E. BARRINGER, president of the American Ceramic Society and chief engineer of insulation of the General Electric Company, gave an interesting account of the manufacture and properties of porcelain for electrical insulation, supplementing his remarks with lantern slides. He showed several pieces of porcelain ware made by the dry process for low voltages and by the wet process for high voltages. One of the interesting features of his talk was the description of a continuous kiln fired in the center with the material going in at one end, gradually approaching the hot center zone and being drawn out at the cool end. This kiln saves 50 to 60 per cent of the heat used in an intermittent kiln.

Dr. A. V. BLEININGER, of the Bureau of Standards, Pittsburgh, Pa., took up a discussion of the physical and chemical characteristics of porcelain, explaining the effect of the various constituents on the final product. The Bureau of Standards has done a great deal of work in the study of porcelain, which is of great value to our manufacturers.

In the discussion Dr. W. D. Bancroft, of Cornell University, suggested that straight sillimanite would be an interesting product to study, not so much from commercial considerations but from a theoretical standpoint. Dr. Bleininger said the potential difficulties were very great in producing this. Mr. R. C. Schroth, Jr., president of the Laboratory Supply Company, Columbus, Ohio, agents for the Ohio Pottery Company, said this company had conducted considerable research in the last two years and that they were firing at the high temperatures used abroad. Several samples of this company's chemical porcelain were on exhibit.

Methyl Alcohol and Acetone as By-Products of the Soda Pulp Industry*

By Alfred H. White and John D. Rue

The introduction of lime as an agent for the disintegration of straw for paper-making is attributed to the Chinese, and the process was in use in Europe in the seventeenth century. The use of caustic soda under pressure for the manufacture of pulp from straw was introduced by M. A. C. Mellier, of Paris, who took out a French patent in 1854 and United States patent 17,387 in 1857. The real development of the woodpulp industry came in America, although based on patents of Watt and Burgess, of London, who in 1853 took out an English patent, and in 1854 an American patent, 11,343, whose rights were assigned to Messrs. Ladd and Keen, of New York.

The first plants for the operation of their process seem to have been erected at Royers Ford, Pa., and later at Manayunk, near Philadelphia, by the American Wood Paper Company.

*Read at the annual meeting of the Technical Association of the Pulp and Paper Industry, New York, February 7, 1917.

The American practice early differentiated itself from European by the use of more concentrated caustic liquors, so that the recovery of the soda by evaporation of the black liquors and incineration of the residue was a feature of the process almost from its infancy in this country. The attempts made in Germany and Scandinavia to cook with weak liquors which might be wasted were not commercially successful, and the American system was introduced into Europe soon after 1870. After its introduction the Germans made important improvements in methods of washing the pulp, concentrating the black liquor and calcining the soda.

The system of alkali recovery in the early mills was copied somewhat from the Leblanc soda process. The liquor was concentrated in a series of pans heated by direct fire, and the liquor passed from pan to pan, approaching nearer the fire each time. The thick mass was finally calcined in an open pan. Attempts to still further utilize the heat of the gases from the calcining furnace led to the construction of towers through which the dilute black liquor fell in a spray or tumbled down over a series of shelves against the flow of the hot gases.

The introduction of the multiple effect evaporator marked an important step in the industry. The evaporator was what is now the well known Yaryan type, invented by Homer T. Yaryan of Toledo, Ohio, in 1886. It was developed and adapted to the concentration of waste liquors from the soda mills by Augustus G. Paine of New York, who in 1890 consolidated several mills under the name of the New York and Pennsylvania Company. To this same company is due the introduction of the rotary kilns for burning the concentrated black liquor. A patent on this feature taken out by L. D. Armstrong of the company in 1892 (U. S. Patent 480,702), and patents were also taken out by S. D. Warren & Co. of Boston, Mass. The commercial problem was worked out by the two companies in collaboration, and the type of rotary then developed is still in general use in soda pulp mills. The organic material in the concentrated liquor is nearly sufficient to complete the evaporation and maintain the required amount of combustion. Some of the waste heat is used to generate steam in boilers set into the flues. No attempt is made in the present process to recover any valuable product but the alkali.

Our own interest in this subject has been in trying to recover methyl alcohol and acetone by destructive distillation of the black liquors. We have been assisted in this both in the laboratory study and in the tests on the larger scale by the New York and Pennsylvania Company, to whom we wish to express our thanks. Our acknowledgments are especially due to Mr. George K. Spence and Mr. John Krauss, chemists at the Clarion mill, for their unfailing courtesy and assistance.

THEORETICAL

The process of destructive distillation of wood to produce methyl alcohol, acetic acid and charcoal is an old one. The question as to the constituents of the wood which produced these products has, however, had little study. Klason¹ has pointed out that the alcohol must come from the lignin, since the destructive distillation of cellulose gave no alcohol in his tests. We have in the main confirmed his results since the destruction distillation of soda pulp, which is not entirely free from lignin, gave in our tests only 0.06 per cent by weight of methyl alcohol, while hardwood pulp chips gave 1.47 per cent by weight. It is therefore evident that the material of the wood which produced the alcohol went into solution in the soda digester or was decomposed entirely and evolved as gas.

Indirect evidence is afforded by the tests of Bergström and Fagerland², who determined the amount of methyl alcohol evolved with the gases given off during a sulphate cook and found that 1.3 per cent on the weight of the pulp, or perhaps 0.65 per cent on the weight of the wood, was converted into alcohol during the cooking process.

The total methoxy groups in the wood as determined by digestion with strong hydriodic acid is frequently assumed to give the maximum amount of methyl alcohol which can be obtained from a given substance. Benedikt and Bamberger³ tested wood in this way and obtained indicated maximum yields of methyl alcohol varying from 4.38 to 6.52 per cent by weight of the wood, according to the species. This figure is so large that it is evident that there must still be possibilities for considerable alcohol recovery from the waste liquors. Streeb⁴ showed that the methoxy content of the lignin acids precipitated from black liquors by mineral acids was between 5.78 and 5.98 per cent. Attempts were made by H. Lowe in 1861 and Tessie du Motay in 1871 to precipitate the organic matter by carbon dioxide to facilitate the recovery of the waste lyes, but their results were not commercially successful. Rinman⁵ has patented a process similar to this involving precipitation of the humus matter by carbon dioxide or stack gases and destructive distillation of the solid residues. Our own experiments have shown that lignin from hard wood precipitated in this way gives on destructive distillation 1.62 to 2.20 per cent by weight combined alcohol and acetone, which is only about two-thirds as much as an equivalent amount of highly concentrated black liquor gives when distilled under the same circumstances.

LABORATORY TESTS

Attempts to distill this concentrated black liquor by heating the full charge in a still such as might be used for tar gave much trouble. The liquor foamed badly and after the destructive distillation was started an exothermic reaction developed which caused a violent evolution of gases. The process of feeding the liquor gradually into an inclined preheated retort gave much better results. In this way successive films of the liquor were subjected to distillation at an even temperature. Not only could the temperature be controlled, but also the length of time which the vapors remained in the hot retort and the extent of the contact with the charcoal, which latter agent has been shown to have a powerful catalytic effect. Experiments showed that the best results were obtained at temperatures even lower than those usual in wood distillation, provided an adequate time was allowed. The temperature of 550 to 600 deg. Fahr. (288 to 316 deg. C.) seemed most desirable.

The laboratory retort used for these tests was made from a piece of gas pipe 3 in. in diameter and 18 in. long which was set in an inclined position. The liquor entered continuously through a side arm at the middle of the retort and the gases left at the upper end. The results of a series of seven consecutive tests with this retort on liquor averaging 41.3 deg. B. are given in Table I. The average result of the seven tests shows 3.81 per cent by volume of methyl alcohol and 0.56 per cent by volume of acetone in the aqueous distillate. Five of the tests are on liquors from hard wood, mostly beech, and two are from the soft wood, mainly bass wood. It is noteworthy that this soft wood which, if distilled directly, would yield very little alcohol, gives fully as good results after the soda treatment as does the hard wood. Other tests on popular and jackpine liquors have shown

¹Papier-Fabrikant, 7, 27-32, 78-82, 104-6, 129-31 (1909); 8, 970-1, Monatshefte, 11, 260-7, 1890.

²Dissertation Göttingen, 1892.

⁴Ztr. f. angewandte Chem., 23, 1252-7, 1910.

good yields of methyl alcohol, though the conditions necessary for the best results have not been worked out.

In this series of Table I the rate of feeding was such that the vapors stayed in the retort from 15 to 30 seconds. Under these circumstances the liquor as it entered the retort foamed and was charred almost immediately, so that the whole interior space of the retort became speedily filled with a very porous black ash which offered a very large amount of contact surface. In some tests the upper part of the retort was filled prior to the test with a wire basket containing black ash, to give more contact surface. This did not seem to be neces-

TABLE I—LABORATORY DISTILLATIONS OF BLACK LIQUOR FROM SODA PROCESS IN RETORT MADE FROM 3-INCH IRON PIPE

Test No.	Specific Gravity of Liquor in Degrees Be	Kind of Wood	Volume Per Cent of Aqueous Distillate	COMPOSITION OF A JUGS OF DISTILLATE, PER CENT BY VOLUME		Average Retort Temperature, Degrees F.
				Methyl Alcohol	Acetone

Aver.	41.3		65.5	3.81	0.56	

sary at the higher temperatures but did give better results at the lower temperatures. Test Number 3, of this series was distilled at a temperature of 555 deg. Fahr., which was entirely satisfactory in other cases, but in this test the liquor was fed at a rapid rate so that the gases stayed in the retort only eight seconds, as against the fifteen or thirty seconds of the other tests. In this test the destructive distillation was complete, as shown by the well charred black ash, but the combination of low temperature and short time showed its effect in the large volume of distillate, 76.0 per cent by volume, and the low yield of alcohol and acetone, which together amounted to only 1.96 per cent by volume of the distillate, whereas the average of the other tests gave 4.37 per cent.

LARGE SCALE TESTS

It was evident from the laboratory tests that in order to obtain good yields of alcohol and acetone it was advisable to conduct the distillation rather slowly and at a temperature well below a red heat and not necessarily above 550 deg. Fahr. This temperature is no higher than that of the waste gases from many steam boilers and made it evident that steel could be safely used as the retort material. The greatest practical difficulty in transferring the process to a large scale came from the rubbery nature of the product during the initial stages of the treatment. Starting as a thick syrup at 40 to 42 deg. B., it changes as the water is driven off to a mass which is sticky and plastic while hot and tough and hard while cold. It also foams strongly during the first stages of the destructive distillation.

The two previous experimenters who have recorded their work in this field have both emphasized the difficulties in handling this material. Meyer⁴ proposes to absorb the thick syrup in briquettes of charcoal previous to the distillation, and Sandberg⁵ uses a combination of mechanical scrapers and screw conveyors to work the material through the retorts. The authors have found it preferable to allow the liquid to flow as a film over the inside of the retort and build up an increasing thickness of charcoal, and then discharge the retort altogether and start afresh.

Both vertical and inclined retorts have been tested. The vertical retort was rectangular, 12 by 18 in. in cross section and 10 ft. in height above the grate bars. The top was closed by a lid in a liquor seal that also served as the means of introducing the liquor which trickled over the edge of the retort and ran down the sides, charring as it went. It was found, however, that the liquor ran down the hot sides of the retort so rapidly that it reached the bottom while still liquid and collected in a pool at the bottom of the retort. The catalytic effect of the carbon was also much less in this large retort than in the laboratory retort, so that the best results were obtained when the vapors stayed in the retort 75 seconds instead of the 15 to 30 seconds necessary with the smaller retort. Even under these conditions the yields were only about 60 per cent as much as those with the smaller retort.

The next attempt was to use an inclined retort which was merely the laboratory retort on an enlarged scale. After preliminary tests to determine the proper angle a battery of twenty-four retorts was constructed. Each retort was made from steel well casing 9.6 in. in diameter and 12 ft. long set with the upper end 3 ft. higher than the lower. This bench was operated twenty-four hours a day for three weeks without any serious operating troubles. The black ash was well charred and leached to a colorless solution, leaving a soft and porous charcoal. There was absolutely no volatilization of soda ash from the retorts, showing that the loss of soda from the rotaries could be entirely eliminated. The doors of the retorts were not properly made and could not be closed tightly. If suction was kept on the retort air leaked in and destroyed some of the products. If there was back pressure on the retorts the gases leaked out and some of the distillate was lost. An inadequate condenser also caused loss. Because of these defective details the average results were lower than they should have been.

For short periods of time as good results could be obtained as on the laboratory scale but, as the average of a day's run, the strongest distillate obtained was when 439 gal. of 40.1 deg. B. liquor from bass wood were distilled and gave a distillate containing 2.75 per cent by volume of methyl alcohol and 0.46 per cent acetone, which is about 75 per cent of the strength obtained on the laboratory scale. There does not seem any reason to doubt that, with leaks eliminated, this apparatus could give results in every way as good as those obtained in the laboratory. The capacity of this plant was 1 gal. of concentrated liquor per retort per hour or 576 gal. per day of twenty-four hours for the unit installed. It was an experimental plant with the feeding of the liquor and discharge of the black ash controlled by hand, which made the labor cost altogether too high for commercial operation. The chief problem still remaining is that of designing efficient machines for replacing hand labor in these operations.

In this particular installation natural gas was burned, but tests for several successive days showed that the black ash as it came from the retort could be completely burned on grates below the retorts, fused white soda ash dripping through the grate and collecting as stalagmites in the pit below. This procedure is not, however, wholly advantageous, since there is loss of soda mechanically carried off with the smoke gases just as there is from the rotaries. Better practice would involve leaching the black ash as usual and then burning the leached wet carbon in gas producers or, after drying by waste heat, burning it directly on grates or in the form of powdered fuel.

The yields to be obtained from the destructive distillation are shown in Table II, calculated to a basis of 1000 gal. of 40 deg. liquor and also to a basis of a cord of

⁴U. S. P. 407, 442 July 23, 1888
British patent 23,125 of 1912

wood. The figures given are really for hard wood, but the yields from soft wood per 1000 gal. of black liquor are practically the same and the yields per cord of soft wood need to be corrected only for the difference in the weight per cord to make them approximately accurate. The yields of methyl alcohol and acetone are all based on analyses of the distillates, since no refining tests on the large scale have been made. No difficulties in the refining process, however, have been indicated by the

TABLE II—YIELDS FROM DESTRUCTIVE DISTILLATION OF CONCENTRATED BLACK LIQUORS FROM SODA PULP PROCESS

Composition of black liquors of 40° B _e :		
	Percentage by Weight	Pounds per 1,000 Gals.
Water	31.7	3,640
Organic matter	40.0	1,600
Ash	28.3	3,260
	100.0	11,500

Yields from 1,000 gals. Black Liquor of 40° B _e :			
	Percentage by Weight	Pounds	Gallons
Aqueous distillate	41.6	4,790	575
Tar	5.9	650	71
Black ash	44.5	5,120	...
Gas (by diff.)	8.3	940	...

		Percentage Composition	
		Pounds	Gallons
Methyl alcohol	3.81 by vol.	145.0	21.9
Acetone	0.56 by vol.	21.6	3.2
Ammonia (as NH ₃)	0.04 by wt.	4.6	

Yields per Cord of Wood put into Digesters:

Based on 890 pounds of soda ash per cord of wood weighing when chipped 44,100 pounds 890 pounds of soda ash are found in 273 gallons of 40° liquor.

273 gals. 40° liquor yield 157 gals. aqueous distillate, containing:

6.0 gals. methyl alcohol 100 per cent.
.9 gals. acetone
6.9 gals. alcohol and acetone.

laboratory distillations. The distillate contains no acid and therefore iron condensers and stills may everywhere replace the more expensive copper. Neither is there any need of the expensive first distillation of the entire liquor which the wood distillers must make to separate the acetic acid from the tar. The liquor as it comes from the tar separating tanks is practically in the same stage as that from the wood distillation after the first distillation has been completed and the acetic acid has been neutralized.

TAR

The tar forms about 11 per cent by volume of the total distillate from hard wood. It has a specific gravity of 1.10 and a pungent odor entirely different from that of either wood tar or coal tar. On distillation, according to the method of Church,¹ it gave the following results:

Journ. Ind. and Eng. Chem., 3, 227-233, 1911; 5, 195-6, 1913.		Per Cent
Water	8.6	8.6
Oil below 100 deg. C	1.7	1.7
Oil 100-205 deg. C	5.4	5.4
Oil 205-270 deg. C	47.3	47.3
Soft pitch	35.9	35.9
Total	98.9	98.9

It contains nearly 50 per cent of distillable phenols, the fraction from 205 to 270 deg. C. being composed of phenols to the extent of 80 per cent. On mixing with formaldehyde and an alkali, this fraction polymerizes to a plastic substance even in the cold and on heating it yields a solid body. The tar is an interesting material, but its value is as yet entirely unproven.

ALCOHOL IN STEAM FROM SODA DIGESTERS

A small pipe with a condenser was connected to the relief line from one of the digesters, and a portion of the steam allowed to blow off during the cook was condensed and tested for alcohol and acetone, with the following results:

Composition of Condensate from Soda Digester

A—Using Hard Wood

Steam on at 11:30 A.M.

Up to 115 lb. pressure and relief valve opened at 1:15 P.M.

Hourly Sample	PER CENT BY VOLUME		Per Cent by Weight Ammonia (NH ₃)
	Methyl Alcohol	Acetone	
1	1.00	0.02	...
2	1.48	0.06	...
3	1.43	0.07	...
4	1.37	0.07	...
5	1.35	0.09	...
Average	1.32	0.06	0.06

B—Using Bass Wood.

Steam on at 6:50 A.M.

Relief valve opened at 8:40 A.M.

Hourly Sample	PER CENT BY VOLUME		Per Cent by Weight Ammonia (NH ₃)
	Methyl Alcohol	Acetone	
1	0.62	0.03	0.026
2	0.80	0.04	0.026
3	0.44	0.04	0.023
4	0.39	0.04	0.021
Average	0.61	0.04	0.024

It was not feasible to measure the steam given off from each digester, but it was estimated at 145 gal. per digester. This would indicate a loss of about 2 gal. of alcohol and acetone from each digester of hard wood and about half that from each digester of bass wood. It did not seem feasible to condense any of the steam from the charge as it was dumped, but that given off immediately after the digester was discharged would undoubtedly have contained as much alcohol as that from the last sample during the cook. The amount of ammonia formed (0.06 per cent) is small but interesting. The values indicated here are too small to warrant recovery in an independent plant, but would probably be worth recovering as a side issue in a plant equipped for destructive distillation of the black liquors.

COST OF OPERATION AND RETURN

The process discussed here merely replaces the rotary calciners by suitable retorts operating at temperatures well below a red heat. The multiple effect evaporators before the process and the leaches after the process need not be changed. The question concerns the cost of installation and operation of the retorts, condensers, etc., as compared with the rotary calciners. No fuel need be purchased to heat the retort since the carbon from the black ash will provide the necessary heat. One thousand gallons of 40 deg. black liquor contain only 3640 lb. of water and yield 2100 lb. of carbon after leaching which is in the ratio of 1.74 lb. of water per pound of carbon. The destructive distillation evolves heat so that the only work which the fuel has to perform is to heat the material to 600 deg. Fahr. and to vaporize the water. The

temperature of the stack gases is as low as that of the average steam boiler and on a basis of steam boiler performance a half of the carbon should be sufficient to heat the retorts and supply sufficient waste heat to dry the leached carbon in waste heat driers. It is therefore conservative to assume that if the carbon is not more valuable for other purposes it will be sufficient to cover all fuel requirements of the plant.

The absence of acid from the distillate makes it unnecessary to use copper in the condensers or stills and also eliminates the necessity for the complete distillation with high pressure steam or in vacuum to separate the acetic acid from the tar. The steam requirements

TABLE III—ESTIMATED COST OF OPERATION AND RETURNS FROM BY-PRODUCT PLANT BASED ON ONE CORD OF WOOD COOKED IN SODA DIGESTER

To be Credited to By-Product Plant per cord of wood:		
6.9 gallons 95 per cent methyl alcohol and acetone @ \$1.10	\$3.76	
41.5 lb soda ash (5 per cent of total, now lost in stack gases)	0.44	
570.0 lb carbon counted here only as fuel		
Saved by elimination of present rotary kilns	0.67	\$3.87
To be Charged against the By-Product Plant per cord of wood:		
Cost of plant estimated at \$1,170 for each cord per day—		
Labor	\$0.80	
Steam and power	0.35	
Superintendence, supplies and taxes	0.20	
Repairs at 10 per cent of cost of plant	0.33	
Depreciation at 10 per cent of cost of plant	0.33	2.01
Balance in favor of By-Product Plant per cord of wood		\$1.86

are therefore much lower than in a wood distillation plant. The chief difficulty remaining in the commercial development of the process is that of developing proper mechanical devices for opening and closing the retorts and for pushing the contents. Since a plant must be composed of large numbers of small units one man must be able to operate a machine handling a number of retorts simultaneously.

The estimated cost of operation and the returns from a by-product plant of this type are tabulated in Table III. The methyl alcohol and acetone figures are taken from the analytical data as 100 per cent strength and in the absence of actual data on refining losses, 5 per cent loss has been assumed and a further allowance made by not giving to the acetone a higher price than the methyl alcohol. The prices used in the table are those prevailing before the war. The carbon remaining after leaching the black ash is assumed merely to serve as fuel for the plant, though it has been shown to be saleable as a paint pigment and has interested the manufacturers of black gunpowder. No value at all has been assigned to the gases, or the tar which would serve as fuel if it could not be more advantageously utilized. The estimated saving of 5 per cent of the total soda ash in circulation is believed to be conservative, as is also the saving of labor, fuel, repairs, and depreciation on the present type of rotary kiln plant for calcining the black liquor.

Summary

It has been shown both by laboratory tests and by larger mill tests that the concentrated black liquors from the soda pulp process may be subjected to destructive distillation so as to yield 6.9 gal. of alcohol and acetone per cord of wood placed in the digester. The yield from a soft wood such as bass is as good as that from a hard wood such as beech. The only variation from the present process consists in replacing the rotary calciners by retorts in which the liquor is distilled at a temperature of about 600 deg. Fahr. If a 40 deg. Baume liquor is used the distillate contains about 4.4 per cent by volume of alcohol and acetone, no acid, and about 11.2 per cent by volume of tar which contains nearly 50 per cent of phenols. The black ash leaches readily to a clear liquid and the recovered carbon is sufficient to provide the necessary fuel for the whole by-product plant. The by-product plant will effect an additional economy by pre-

venting the present loss of soda which is carried as dust up the stack from the rotary calciners. The net saving by the introduction of a by-product plant is estimated, as shown in Table III, to be \$1.86 per cord of wood cooked in the digester.

University of Michigan.

Current News and Notes

Second Annual Convention of Technical Association of Pulp and Paper Industry.—The second annual convention of the Technical Association of the Pulp and Paper Industry was held at the Waldorf-Astoria, New York, Feb. 6, 7 and 8, 1917, in conjunction with the general convention of the American Paper and Pulp Association. Tuesday, Feb. 6, was given over to executive committee meetings. On Wednesday morning a general session was held, and on Wednesday afternoon a session for the presentation of papers was held. A paper presented at this session by Profs. Alfred H. White and John D. Rue of the University of Michigan on methyl alcohol from spent liquors will be found printed in full elsewhere in this issue. On Thursday morning another session was held for the presentation of papers. The attendance was very good, and a lively interest was shown in all the subjects discussed.

National Lime Manufacturers Meet in New York.—The National Lime Manufacturers' Association held its fifteenth annual meeting at the Hotel Astor, New York, on Feb. 6 and 7. The president of the association, Mr. Wm. E. Carson, presided at the meetings. An interesting series of papers were read, taking up such subjects as revision of standard specifications for hydrated lime, discussion of barrels and packages, welfare work, trade acceptances, use of pulverized coal in lime kilns, group insurance, calcining of lime, continuous hydration and other subjects. G. F. Loughlin of the Geological Survey, author of the annual report on lime, gave an interesting talk on the work of the Survey in obtaining statistics. He said he was working up statistics on magnesium lime and dolomite, in view of their being the future raw materials for our magnesium industry. The members had a rare treat on Wednesday morning when Robt. Lee Montague of Montague, Va. ("42 miles from any railroad"), related a series of anecdotes of Virginia life. He is a natural talker, and his stories from life were rich in humor, and kept the audience in a continual uproar. On Wednesday morning a silver loving cup was presented to Lawrence Hitchcock for his work in establishing and successfully conducting the hydrated lime bureau.

French National Laboratory of Physics and Mechanics.—The Academie des Sciences, according to *Genie Civil*, has resolved to establish a National Physical and Mechanical Laboratory, for the purpose of scientific research directed toward industrial uses. The laboratory will be controlled by a council, of which half the members will be nominated by the Academy, one-fourth by the State Department, and the remainder by the chief industrial associations. The executive control will be in the hands of a small technical committee. Existing laboratories engaged on similar work will be affiliated to the National Laboratory, and will work in close relationship with the latter. Substantial funds will have to be provided for the working expenses of the laboratory, and for the assistance of the affiliated institutions.

Dyestuffs Appropriation.—The Senate has passed the Agricultural bill, which contains a provision for the appropriation of \$49,400 for research in dyestuffs. The money will be used by the Bureau of Chemistry.

Air Drying

By Carl Hering

In some industrial processes the moisture in the air is objectionable, either because the water is an undesirable foreign material, or because it interferes with the use of the air for drying operations; its variability is another objection, as also its tendency to promote bacteriological growth; extreme desiccation acts as a food preservative. In the operation of drying objects in the air, the time required increases rapidly as the air is more nearly saturated, and the objects to be dried are, of course, never any drier than the air which was last in contact with them and which is, therefore, approaching its saturation point on account of the added moisture from the objects. Moreover, the evaporation of the moisture in the objects produces a lowering of the temperature, and this in turn lowers the drying power of the air because the lower the temperature of air carrying a definite amount of moisture, the more nearly is it saturated. Replacing the air rapidly or heating it, are the usual methods for diminishing these objections, but in some cases, as for instance, in the drying of grain, foodstuffs, photographic films, etc., the high temperature and the dust carried by moving air are both objectionable, and on warm, humid days in summer it is sometimes physically impossible to dry such objects properly.

In blast furnaces the water carried by the air robs the furnace of a certain amount of heat, as it must be heated to those high temperatures and is no doubt dissociated also. On a humid summer day, for instance, the amount of water entering a modern blast furnace with the air is about 4 to 5 gallons per minute, which is about equal to what will run out of a large house spigot. It is, however, not quite as bad as though such a formidable stream of water were forced as water into the furnace, as is sometimes alleged, because in the form of vapor in the air the water already contains its latent heat of vaporization, and therefore does not rob the furnace of that formidable amount of energy. In blast furnaces one of the chief objections to the moisture is its variability, making it difficult, if at all possible, to get uniformity of the iron produced.

In the fires of steam boilers this moisture robs the fire of the heat which this water vapor carries off as a dead gas into the chimney. Those who claim that by being dissociated into oxygen and hydrogen at those high temperatures, it adds valuable combustible materials, seem to forget that it first had to rob the fire of exactly as much energy for its decomposition as these two gases give up on uniting again, as they seem to appear in the chimney as steam.

Damp air being very bad for consumptives and as it encourages bacterial propagation in general, it might sometimes be desirable to dry the air in rooms for sanitary purposes.

There are, therefore, cases in which it is of great importance to desiccate the air to a greater or less extent, and many others in which it would be desirable if the cost is not prohibitive. It is, therefore, often a question of the calculation of the cost, and as this cost increases with the degree of extraction of the water, it is also a matter of calculation to find how far it pays to go in the degree of drying.

A number of methods are available. Heating the air reduces its degree or percentage of saturation, and it, therefore, takes up more water with greater facility; and if heated under constant pressure, as for instance, under atmospheric pressure, it reduces the amount of water per cubic foot of the air because the air has expanded; but it does not diminish in the least the

amount of water in a given quantity of air, both measured in pounds, and is therefore, not a process of drying the air.

Reducing the pressure by creating a partial vacuum, increases the drying capacity of the air because the water in the objects then tends to vaporize more readily. The low pressure air itself is really wetter then, in that it contains more water per cubic foot or per pound; hence this is only a process of drying objects, but not of drying the air itself. The water may be said to be sucked out of the objects.

Compressing the air deposits some of the vapor in the form of water and is therefore a true partial desiccation. Such compression, however, also heats the air which itself tends to lower the degree of saturation, and the latent heat of the water which has been condensed, must also appear somewhere as sensible heat. If cooled while compressed in order to get out more of its water, the air will be still colder when expanded again, and this increases its degree of saturation until reheated. Moreover, at the low temperatures produced by expansion there is great danger of ice forming in the valves, which clogs them. This process, therefore, involves complications besides the transferences of heat and the use of relatively large moving machinery; its application is, therefore, limited.

Liquefying the air and then evaporating it again dries it absolutely, as the moisture (besides the oxides of carbon) is all frozen in the process and can be filtered out as a solid. It is one of the few methods for producing absolute dryness, but is expensive, though by using a suitable heat regenerator this cost ought to be very greatly reduced and perhaps it might then be commercial; absolute dryness, however, is seldom required.

Concentrated sulphuric acid, solid chloride of lime, and other moisture absorbing materials, are simple and effective ways of very slowly drying a small amount of confined air, and are much used on a small scale, to which, however, the cost limits them. They are said to absorb even extremely small quantities of moisture and may, therefore, be classed among the absolute methods.

Centrifuging the air at very high speeds ought to concentrate the moisture in one part, and perhaps to oversaturation, thereby rendering the other part drier; but the expense would probably be prohibitive.

But of all the methods of drying, the one based on cooling is the most practical one when dry air is required on a relatively large scale. When the temperature of air containing moisture is reduced to below the so-called dew point (the temperature at which that amount of moisture saturates it) the excess of moisture above saturation at that lower temperature, is condensed as water or ice and may, therefore, readily be separated. At that lower temperature it is then saturated, which means that it will hold or take up no more water, but if heated again to its original temperature after the excess of water has been separated from it, the air will be drier to the extent of the amount of water or ice which has thus been condensed from it; and the lower this temporary temperature was, the greater will have been the extraction, though not in proportion. While this is only a partial desiccation, unless carried to an extreme like in liquid air, yet with modern ammonia ice machines it is theoretically possible to so reduce it that when heated again to normal temperatures, the humidity will be only 2 to 4 per cent, which might well be termed "bone-dry air" and which probably never exists naturally.

As stated above, the applicability of this method generally depends on the cost, and this cost varies with the degree of extraction; hence a predetermination of this cost becomes important. Except in the simplest

cases the calculations are quite involved when all the factors are taken into consideration, and when precision is desired; they should, therefore, not be attempted by those who do not understand them. But roughly approximate calculations are easily made with the aid of conveniently arranged tables.

The principles involved in this process, on which the calculations are based, are as follows: Atmospheric air always contains some water, though it is rarely saturated. The amount of water, termed the humidity, is usually stated in per cent, which is 100 times the ratio of the actual amount to the amount it would contain at that same temperature if saturated; it is measured with the wet and dry bulb thermometers, the readings of which are interpreted by means of tables, as is well known. Care must be taken with the measurements made with the wet bulb, as the rate of fanning or "ventilating" has an important effect if insufficient.

To dry this air it must be cooled first down to the so-called dew point, that is, the temperature at which the water which it contains saturates it. In this first stage of the process the moist warm air follows the laws of gases, and the energy required to be extracted is determined from the specific heat of air and that of the constant amount of moisture contained.

If then cooled below this saturation temperature it begins to deposit its water, and from there on down the air is always saturated at the respective temperatures, hence it no longer follows the laws of gases, but those of saturated vapors. During this stage the energy to be extracted consists of three parts, the two parts necessary to cool the air and the water in it, and the third, the latent heat of as much of the water as has been condensed. If this temperature is below freezing there must be added a fourth part, the latent heat of the amount of ice formed.

Of these parts by far the two largest ones are those for the cooling of air and for the condensation, and of these the former is generally larger than the latter. The freezing energy is relatively much smaller and that to cool the moisture is a small amount, only a few per cent.

After the extraction the air with whatever moisture it still contained at saturation at the lowest temperature must then be reheated which requires a formidable amount of heat. This might be taken from the atmosphere through thin walled metallic ducts and air circulating devices; though the calories then cost nothing, it may be cheaper to heat it more quickly with a heater.

When this dry warm air is then used merely as combustion air in furnaces, the above are all the chief factors entering into the calculations. The duty imposed on the refrigeration machine then is to carry off those calories which must be extracted and which might be termed negative calories, while the duty on the heater is to provide the reheating of the dry air.

But when the dry air is used for drying wet objects, like photographic films or grain, there is an additional and sometimes quite important factor. The vaporization of the water in the objects consumes latent heat. If the drying is done in closed chambers, as it naturally would be, this latent heat will be extracted chiefly from the air and the objects, and will, therefore, cool both. This in turn reduces the drying power of the air and, therefore, the speed of drying. It would also be conceivable that the cold produced by this latent heat energy might freeze the objects; at a uniform temperature of 32° F. the evaporation of each pound of water would freeze another pound. Hence, in such cases the dry air must either be first heated to such a temperature that it will supply this latent heat without cooling itself too much, and this might involve heating it to

a rather high temperature, or if the objects would be injured by this temperature, the air must be heated during the drying operation, or the drying be slow enough to give time to absorb heat from the surroundings.

The cost of this process of drying the air being generally the criterion to decide whether and to what degree it may be practicable to use it, and as this cost may be prohibitive, thermal economies in the process may become quite important, particularly in saving the duty of the refrigerating machine, negative calories, at least at cold temperatures, being far more costly than positive ones in a heater. An accumulation of economies in different parts of the process may together amount to an important saving. An analysis of the most perfect conditions may, therefore, be useful as a guide.

The formidable amount of energy, generally more than half of the total, which must be extracted from the air itself, aside from the water, is, of course, the same in amount as that necessary to reheat it again afterwards, differing only in its sign. It is, therefore, theoretically recoverable by means of a regenerator. If the original warm, moist air be made to pass in one direction through channels with thin metallic walls, and the cold dry air be made to pass in the opposite direction on the other side of those metallic walls, this energy will be exchanged through the thin walls, whereby the ice machine is relieved of that much of its duty, which may amount to about a half; as the moist air then arrives at the refrigerator at a cold temperature, the ice machine would have to supply only the difference; the reheating of the dry air is then also largely saved, as it would come out at nearly the temperature of the incoming air.

Moreover under suitable circumstances much of the water, probably about half or over, would then come out in this regenerator as water, thereby considerably reducing the amount of ice formed and saving its latent heat. As the object is to separate the water from the air, it is taxing the refrigerator unnecessarily to further cool this water after the separation has been effected, and as this usually begins well above the freezing point, some further energy could be saved by having it run off as soon as formed, that is, at the temperature of formation. This would take place in such a regenerator when appropriately constructed.

The cold dried air from the refrigerator cannot, however, take up any more heat in this regenerator than will heat it to the temperature of the incoming air, while the warm moist air could convey to it not only its own heat, but also all the latent heat of the water which is condensed in the regenerator. Hence, additional economy could be obtained, if desired, by cooling the air somewhat more while passing through the regenerator by means of the partially spent cooling liquid or gases coming from the refrigerator. This would take out more of the moisture as water, instead of as ice, and the colder calories of an ice machine cost more than the less cold ones.

In an ammonia ice machine very low temperatures necessarily exist, and as the air will be drier the colder it has been, it would be desirable to make use of these very low temperatures or at least to approach them. This becomes practicable when such a regenerator is used, as the ice machine can then absorb nearly all its calories at quite low temperatures. Makers of ice machines say that -15° F. (-26° C.) can be obtained in regular operation. Cooled to this temperature and then heated again to 70° the air will have a humidity of only 2.95 per cent, hence is extremely dry air. Liquid ammonia boils at -28.6° F. (-3.7° C.), hence as -15°

leaves a margin of 13.6° F., still drier air might be obtained, though the difficulties and the thermal losses increase as the temperature is lower.

Makers say that the efficiency of an ammonia ice machine is reduced 25 per cent by using brine as the conveyor of the cold. Using the ammonia directly would, therefore, increase the capacity of an ice machine 33 per cent and by using refrigerating coils made without joints, by autogenous welding, the danger of leakage in the refrigerating chamber is avoided, and this would make the direct use of the ammonia practicable. It has the objection that steam cannot then be passed through the coils to melt off the ice, as that would contaminate the ammonia with water. But these coils when loaded with ice could for a short time or alternately be used as the ammonia condensers, thereby melting the ice, and at the same time making good use of the negative calories in it.

A common way of producing moderately dry air is to spray it with very cold water. The advantage of this method is its simplicity, the disadvantages are the large quantities of water required to be cooled and forced through the spray nozzles, and that the air is not very dry, though uniformly so. The theoretical maximum dryness would then be 2.11 grains of water per cubic foot or about 0.3 lbs. per 1000 cubic feet at 32° F., and when this is then heated to say 70° F., the air would have a humidity of 24.5 per cent, containing about 0.28 lbs. per 1000 cubic feet, which is not very low, though probably low enough for some purposes.

But these figures represent theoretical perfection and it would require an infinite amount of cooling water. This cooling water must absorb considerable energy in reducing the temperature of the air and in condensing the water, and this energy will, of course, heat this water; moreover the coldest temperature of the air will be that of the cooling water when it is warmest, as it will be the temperature of the water last in contact with the air, that is after it has absorbed this energy. Water, as such, cannot be cooled lower than 32° F., and to cool the air down to say 38° F., would allow only 6° rise, hence enough cold water at 32° would have to be used that it will absorb all this energy and not rise more than 6° F.; the amount will be roughly inversely proportional to this rise. When thus cooled to 38° F. and then heated to 70°, the humidity of the air will be 31.1 per cent, containing about 0.355 lbs. per 1000 cubic feet, which is about 78 per cent of the perfect extraction referred to above.

Assuming the original moist air to be at 70° F., and to have a humidity of about 75 per cent, therefore containing about 0.855 pounds of water per 1000 cubic feet, which is not unusual on a moist day in summer, the cooling water would have to take up a little over 1000 B T U per 1000 cubic feet of air. And as the water is allowed to be heated only 6° F., this means 167 lbs. or about 20 gallons of cooling water per 1000 cubic feet of air for perfect operation. For a blast furnace requiring 45,000 cubic feet per minute it would, therefore, take 900 gallons of cold spray water per minute. The amount of water extracted would be 0.50 lb. per 1000 cubic feet, which is 58.5 per cent, or only a little over half, of what was in it, leaving 41.5 per cent of the water still in the air.

Some improvement in this method may be obtained by passing the air through successive sprays so that it might finally reach more nearly the lowest temperature, 32° F. And the spent spray water of the coldest spray may be used over again for the next warmer one, and so on. A lower temperature than 32° and still have unfrozen spraying water, can be obtained in this method by using a brine for the spray water; the extracted

water will then necessarily gradually dilute the brine which must, therefore, be concentrated again, as by boiling. Using the same water over again also means that it must be filtered, as it contains all the dirt of the air and this might otherwise clog the small spray nozzles. Whether such economies are worth their expense is a matter of computation.

An important advantage of this spraying method is that the air and the cooling water are brought into direct and intimate contact with each other, hence the transference of heat is rapid, and ought to be very nearly perfect. It is for this reason sometimes called the direct method. Whether this advantage is too dearly bought is a matter of computation, and depends also on the particular conditions of the case.

A simple and convenient method of carrying out this cooling process on a small scale is by forcing the warm moist air through cracked ice. If carried out to the extent that the air leaves at 32° F., it will then contain a trifle more than 0.3 pounds of water per 1000 cubic feet, and when then heated again to 70° F., it will have a humidity of 24.5 per cent and contain about 0.28 lbs. per 1000 cubic feet. All the water then leaves at 32° F. and assuming the ice to be no lower than 32°, the extracted heat will all be the latent heat of the ice melted, which is about 144 B T U per pound. Assuming the original air to be 70° F. and to have a humidity of 75 per cent, the cooling will, under perfect conditions, require the extraction of about 1280 B T U, hence the melting of 8.9 pounds of ice, per 1000 cubic feet. Some further economy in this method can be obtained, if desired, by passing the air first through granular material over which the melted ice and extracted water are made to flow or spraying this water into the air before it reaches the ice. Regeneration of the heat in the air itself will add further to the economy. As no useful effect results until the saturation temperature is reached, the ice is being consumed uneconomically until the temperature reached is low. While it costs less ice the lower the original humidity, it is by no means in the same proportion.

For rough preliminary estimates the accompanying Table I may be of interest. It has been reduced to

Table I—1000 Cubic Feet of Saturated Air.

Tempera- ture F°	Pounds of Water	B.t.u. to Reduce from Given Tem- perature to Water at 32°	B.t.u. Per Pound of Water Extracted	B.t.u. to Reduce from 32° to Given Tem- perature	B.t.u. Per Pound of Water Extracted

-10	.0407	...	...	1,060	4,060

1000 cubic feet of saturated air at the given temperatures. The second column gives the contents of water in pounds. The third gives approximately the thermal units required to be extracted in order to reduce the temperature from that given in the first column to 32° F. without freezing any of the water; hence it refers to the best that could be obtained by a single spraying with water at 32°, or with passage through cracked ice. It includes the cooling of the air with its water, and the latent heat of condensation. The figures are only approximate and do not include the smaller factors. The fourth column gives the corresponding rates per pound of water extracted in this way. The fifth

is like the third, except that the cooling begins at 32° and ends at the temperatures given in the first column; it therefore assumes that all the water that condenses at 32° has already been extracted as such; these figures must, therefore, be added to those in column 3 if any freezing is done, and it is here assumed that all the free water at 32° is drained off and is not to be frozen. The sixth column gives the corresponding rates of extraction. The amount of water left in the air can be obtained from the second column and will, therefore, be 0.302 lbs. for all the values in column 4, while for column 6 it will be that given in the second column for the temperature to which the reduction has been carried. As the figures are based on the physical laws and constants the inefficiencies in the process must be allowed for in addition.

If the water is all frozen, which is sometimes done, an additional number of B T U will be required to freeze that which would have run off as such at 32°. These figures assume saturation, hence the B T U required to first reduce the air to saturation must be added. If regeneration is used the B T U in columns 3 to 5 will be considerably reduced; a further reduction in B T U would be obtained by cooling in steps; the figures for the B T U are therefore not the lowest possible.

It will be noticed from column 2 that the amount of water extracted for every 10° drop is far greater at the higher than at the lower temperatures. Also that the cost in B T U for extracting a pound of water increases at the lower temperatures, though perhaps not as greatly as might have been supposed.

For saturated air at 60° F. the B T U to cool the air to 32° are roughly equal to those required to condense the water; above 60° those for the latter form the greater half, while below 60° this is reversed.

Makers of ice machines rate them in tons of ice per 24 hours, which they say means that the machines will do as much cooling as that much ice at 32° F. would do in melting to water at 32°, hence this corresponds to the latent heat of melting ice. The latter is about 144 B T U per pound, hence per ton of 2000 lbs. per 24 hours the rate of cooling produced by an ice machine would be an extraction of 200 B T U per minute; this is based on the use of brine as the conveyor; when the ammonia is used directly the capacity is said to be a third higher. From tests of large ice machines using brine, it would require a little more than one kilowatt to operate an ice machine generating 200 refrigerating B T U per minute.

Philadelphia, Pa.

Magnesite Deposits Being Worked in Washington.—The American Mineral Production Company has begun the production of magnesite and various magnesium salts from large deposits owned by the company in Stevens County, Washington. The deposit lies 5 to 10 miles west of Valley, a small town on the Great Northern, about 50 miles northwest of Spokane. It is exposed in several places to widths of 30 to 600 ft., and is estimated to contain an enormous quantity of magnesite, consisting of a coarse to finely crystalline material of reddish to pinkish color. It is not mixed with as much limestone or dolomite as the Australian magnesite. Analyses across wide areas are as follows:

	Silica		Alumina		Iron Oxide		Magnesia	
No. 1.....	0.80	0.40	2.70	3.30	92.10			
No. 2.....	0.89	none	.58	none	95.00			

A number of chemists and engineers have been working for some time on the property, and it is claimed by the company that it is pure and in larger quantities than the Austrian, which formerly produced 90 per cent of the world's production of this grade of magnesite.

The Effect of Centrifugal Force on Colloidal Solutions*

By Eugene E. Ayres, Jr.

Considerable work has been done on certain centrifugal separations which cannot be accomplished by the highest degree of centrifugal force at present capable of commercial application. Some chemists have expressed surprise that gasoline cannot be separated from kerosene, or that soap cannot be mechanically removed from aqueous solution. Others are inclined to doubt that colloidal gold can be successfully deposited from a clear gold sol.

There is one certain method of eliminating guesswork as to the practicability for a given set of conditions—and that is the experimental method. If a careful trial succeeds or fails, the practicability for that set of conditions is no longer a matter of opinion. But pertinent questions may still be asked. For instance, will the result secured by the test represent the best that any type of centrifugal machine may be expected to secure? Is it possible that a higher degree of force can actually remove anything unaffected by the lower degrees? Is it possible that, although complete separation may have been secured, the components are not separately discharged? Such questions can be correctly answered only by thoroughly understanding the complexity of the task confronting the centrifugal separator.

The Colloid State.—Let us first review briefly a few general aspects of colloid chemistry.

The term *dispersed* has been correctly applied to systems involving every size of particle, from the macroheterogeneous suspension to the true molecular or ionic solution. The term *colloid* in its exact sense designates a state of matter with respect to degree of dispersity within the rather narrow limits defined by sub-micro- and amicro-heterogeneity. The largest colloid particles in this sense are about 0.1 μ in diameter—at the extreme limit of microscopic visibility, and at about the limit of retention by the best clay filters.¹ Particles smaller than 0.1 μ may be seen by use of the ultramicroscope, whose lower limit is about 3 μ . Colloidal phenomena are exhibited by dispersoids whose particles are anywhere from 0.1 μ to 1 μ . Most solutions, or molecular dispersoids, are just beyond this limit, a fair average molecular diameter being about 0.1 μ , although some of the more complex molecules are much larger.²

All these systems are polyphasic, but the disperse phase will confer various sets of properties upon the dispersoid, depending upon the specific surface. Therefore the complex system involving many different degrees of dispersion may be said to have distinct phases corresponding to the three series:

1. Particles larger than 0.1 μ .
2. Particles between 0.1 μ and 1 μ .
3. Molecules.

The second division defines the colloid state in its strictest sense. But many of the phenomena that characterize the true colloid characterize to a greater or less degree the coarser dispersoids, whose particles may be even larger than 5 μ , and can be retained by the ordinary filter paper.³

*A paper read at the Ninth Annual Meeting of the American Institute of Chemical Engineers, New York City, January 12, 1917.

¹The μ , or micron, is 0.0001 cm.

²The μ is 0.001 μ or 0.000001 cm.

³Wo. Ostwald-Fischer, "Handbook of Colloid Chemistry," p. 263.

⁴The diameter of the starch molecule is said to be about 5 μ . Lohry de Bruyn and Wolff, Rec. Trav. Chim. Pays-Bas, 23, 155 (1904).

⁵Ordinary filter paper holds back particles of about 5 μ ; a hardened filter (Schleicher and Schull, No. 602 e. h.), those about 2 μ in diameter. (Wo. Ostwald, l. c.).

Certain classifications of dispersoids have been made without regard to degree of dispersion. It will be unnecessary to discuss these distinctions here except to mention the colloids that tend to form a gel. There are several characteristics of these gel-forming dispersoids, especially affecting centrifugal separation. The particles are usually extremely small—even beyond the limit of the ultramicroscope—and the disperse phase and the dispersion medium are composed of both components.⁵ The solid gel has an enormous viscosity fac-

eighths of the salt from a saturated Glauber's salt solution.

The Problem.—When any dispersoid is subjected to centrifugal force—no matter in what type of apparatus—the separation of any individual particle will depend upon the distance through which it must move in a given time before being considered "separated." There are two types of centrifugal machines. In one case, a container is filled with liquid and rotated. The particle must move until it is held in firm contact with the bottom of the vessel before any separation can be measured. In the other case, the liquid is passed continuously through a rotating cylinder and it is possible to draw the liquid from the point nearest the center of rotation while the machine is still in motion. Separation can therefore be detected when the particle has been moved only a fraction of the distance from the surface to the bottom. Our consideration will be limited to this more convenient type.

It would seem that the whole problem hinges upon the proper calculation of the velocity of a suspended particle acted upon by a force. But what is the force? When we think of velocity, we naturally turn to the law of Stokes.

$$U = \frac{f}{6\pi r\eta},$$

where U is velocity of the particle of radius, r , acted upon by the force f , while the viscosity of the medium is η . The formula is based upon the conception that a small body, acted upon by a constant force, will move through a resisting medium with a constant velocity. The normal acceleration is neutralized by friction. The law was applied first to the fall of raindrops through the air. More recently, a large number of important investigations have been based on Stokes' equation, and its accuracy has been verified for liquid as well as gaseous media, and for colloidal particles as well as raindrops.

J. Perrin¹¹ showed the law to be valid for particles as small as one-tenth of a micron. Einstein,¹² in his work on the coefficient of diffusion, assumed Stokes' law to be correct for molecules larger than one-thousandth of a micron, and his results show his assumption to be correct. On the other hand, M. Pellat,¹³ in his investigation of ionic translation in electrolysis, gives some indication that Stokes' law will require a slight modification when applied to particles as small as the potassium ion. Of course our chief interest is in the relatively large particles to which the law has been found to apply without correction.

We are told, then, that colloids will settle by gravity according to a given formula. Emil Hatschek¹⁴ offers a numerical example in the case of a gold sol, and utilizes the very evidently incorrect result as an interesting clue to certain other factors that make for the stability of colloids.

FIG. 1—CONTINUOUS CENTRIFUGE

Temp.	Concentration Agar.	
	Liquid.	Solid.

5°	0.09	3.0

tor. This would prevent any centrifugal separation even under the most favorable conditions. When the gel is warmed, to liquefy and reduce viscosity, the size of the particle is even further reduced, and the compositions of the two phases tend more nearly to equalize in percentage of components. When this equilibrium is approximately established, the absolute density of the disperse phase is therefore nearly zero.

We shall put aside the gel-forming colloid for the simpler case of the suspensoid whose particles, whether rigid or deformable, have little chemical or solvent affinity for the dispersion medium.

At first glance, it might appear necessary to limit our problem still further. In the case of separation by gravity, the degree of dispersion is likely to change enormously on account of some of the influences commonly known to affect stability. Since time, in the case of centrifugal separation, is a matter of minutes rather than days, we can eliminate these factors.

A Few References.—With reference to the theme of this paper—the study of colloids under the influence of centrifugal force—the first task will be to formulate a mathematical expression of the phenomenon of subsidence. The subject has already been treated in a variety of ways.

The probable influence of gravity on solutions was studied by Gay Lussac. He examined the upper and lower portions of a salt solution in a tube two meters long maintained at a constant temperature for a long time. The results were negative. In 1887, Gouy and de Chaperon, commenting on this work, demonstrated theoretically that the force of gravity was too small. L. Vegard⁶ from thermodynamical considerations, gives an expression for the equilibrium of a solute. H. S. Davis⁷ gives a mathematical analysis of the effect of gravity on a solute, by applying Fourier's law of linear diffusion. His experimental results are also negative.

One of the earliest of the difficult centrifugal separations was made as long ago as 1895 on a mixture of two gases—hydrogen and hydriodic acid.⁸ The gases were whirled for three hours in a machine operated at 2400 r.p.m. with a radius of rotation of 21 centimeters. A 3 per cent difference in concentration was noted.

About twenty years ago, it was observed that subjecting a salt solution to moderate centrifugal force will cause a measurable difference of potential between the center and the periphery. More recently⁹ a centrifuge was successfully employed to obtain a concentration of antitoxic substances in immune sera. Perhaps the most striking work on the centrifugation of solutions was done by Van Calcar and Lobry de Bruyn¹⁰ who were able to crystallize out about three-

FIG. 2

What are these other factors? It is true that if precautions are taken, as recommended by Perrin, Wo. Ostwald, and others, to avoid small convection currents by observing the rate of fall in a capillary tube, the initial rate of fall will correspond to the equation. But after a time the rate will retard and then cease altogether. In other words, the force of gravitation has been neutralized by other forces acting upward, and the system is at equilibrium.

The Dynamics of Colloids.—Just as Van 't Hoff has been the pioneer in developing the analogy of dilute molecular dispersoids to gases, so M. Jean Perrin has done the first work in extending the kinetic theory to colloidal and even subcolloidal degrees of dispersion. Van 't Hoff had shown that the molecules of a solute in dilute solution play the same part as the molecules of a gas—develop the same kinetic energy, and exert a similar pressure on the walls of a semi-permeable membrane.

The earlier work on the osmotic pressure of colloids indicated a small but invariable value—sometimes so small as to raise a suspicion of experimental error or impure sols, but so invariable as to lead finally to the conclusion that all colloids did exert a definite osmotic pressure. Perrin showed that the osmotic pressure of colloids is due to their own kinetic energy, an energy derived from the molecular energy of the dispersion medium by molecular impacts on the colloidal particle. Kinetic energy implies motion, and colloids are found to possess an irregular, translatory motion known as the Brownian movement, from the name of its discoverer.

Osmotic pressure is thus a property common to all dispersoids whose particles are small enough to show Brownian movement. The largest particles showing this movement are about 10μ in diameter—just about visible to the unassisted eye—but their osmotic pressure is negligibly small. In fact, some particles will settle completely by gravity when less than one micron in diameter.

A second property of some dispersoids is an electric charge. The charge may be either positive or negative, and may be caused either by absorption of electrolytes or by an actual ionization of the particles. Naturally, the presence of equal electric charges of similar sense would seem to lead to an electro-repulsion between particles.

Osmotic pressure can be easily measured in a given case by the usual methods of physical chemistry. The size and sense of the electric charge can be measured by the speed of migration in an electric field.¹⁰ This has been done and the conclusion was drawn that the electro-repulsion cannot be great enough to affect subsidence, although it greatly influences the rate of what is termed "agglomeration crystallization." So there remains only the osmotic pressure.

Instead of measuring this pressure and in some way computing its upward component, it is more convenient to start with the law of distribution derived for colloids by J. Perrin.

The Law of Distribution.—Imagine a liquid containing a number of small particles of uniform size and distributed uniformly throughout the liquid. After the system has been allowed to stand for a time, the particles will have arranged themselves in a definite order. The concentration (number of particles per unit volume) will be greatest at the bottom, and will vary in an exponential manner with the height according to the equation:

$$\log_e \frac{c_0}{c_x} = mgkx,$$

where c_0 is the concentration of particles at the initial level, o , (see Fig. 3), c_x is the concentration at the height x , m is the mass of the particle, g is the acceleration of gravity, k is a constant.

If we put

$$mgk = \alpha,$$

we may write the expression

$$c_x = c_0 e^{-\alpha x},$$

In order to determine the concentration at any point, x , we assume an empirical initial concentration—in

FIG. 3

other words, we take a value, k_1 , to represent the number of particles in a unit volume when the system was uniform.

we can now write

$$k_1 = \int c_x dx = \frac{c_0}{-\alpha} e^{-\alpha} + c'.$$

The depth of liquid is conveniently taken as 1 centimeter. We can therefore integrate between the limits, 1 and 0.

$$k_1 = \int_0^1 c_x dx = \frac{c_0}{-\alpha} [e^{-\alpha} - 1],$$

whence

$$c_0 = k_1 \left(\frac{\alpha}{1 - e^{-\alpha}} \right),$$

and

$$c_x = k_1 \left(\frac{\alpha}{e^{\alpha x} - e^{\alpha(x-1)}} \right).$$

By the substitution of any value of x between 1 and 0 we can find the concentration at x as a function of k_1 and α .

You will remember that

$$\alpha = mgk.$$

k is a constant equal to Avogadro's constant divided by the product of the perfect gas constant and the absolute temperature. Assuming a normal temperature, the constant k is about equal to 3×10^9 , in c.g.s. units. The mass, m , is equal to the volume times the absolute density, d .

$$m = \frac{4}{3}\pi r^2 d;$$

$$\alpha = \frac{4}{3}\pi r^2 d \cdot 980 \cdot 3 \cdot 10^9;$$

$$\alpha = 10^{11} \cdot r^2 d.$$

For particles of different sizes and densities, α can be easily computed and substituted in the formula for concentration, from which the condition at equilibrium

¹⁰The Svedberg. Koll.-Zeitschr., Vol. VI, 238 (1910).

can be shown for any value of α . It is more convenient to express k_i as a weight percentage.

The following tabulation will give a fair idea of the various arrangements with different values of α .

α	c_1	c_2	c_0
1	0.58	1.04	1.60
10	0.001	0.10	10.00
100	10^{-10}	10^{-10}	100.00

In each case, the initial concentration, k_i , was taken as 1 per cent.

Similar values can be easily computed for any other values of α or for smaller or larger values of α , or for other values of k_i .

It is seen that the arrangement at equilibrium is a function of α . But α is the product

$$10^{23}rd$$

so that the radius of the particle that will give a certain α will depend upon the absolute density, d . Thus, when $\alpha = 1$, a particle of low density must have a radius of 10^{-5} centimeter, whereas if the density is high, the radius must be 10^{-6} .

The condition represented by $\alpha = 100$ leaves no room for doubt. Gravity separation will be complete. In such a mathematical application, the liquid can never have a concentration at any point equal to absolute zero, because in such a case the equation for distribution would be indeterminate. But such concentrations as, for instance, 10^{-10} per cent, can be considered as practical zero. The condition represented by $\alpha = 10$, also means a very thorough separation. When $\alpha = 1$, the separation, though not at all complete, is still easily measurable.

It is interesting to note that Zsigmondy found the gravity subsidence of a gold sol to be measurable when the particles were about 75μ in diameter. Such a particle with the high density of gold would make α equal to about 1. Occasionally we come across statements that particles usually will not settle by gravity when as small as 0.1μ . Theoretically the condition of equilibrium shown for $\alpha = 1$ should obtain unless the electromotive forces should bring about agglomeration crystallization. In this case, subsidence will be complete.

We might stop to compute the effect of gravity on the distribution of true solutions where α is very small, but we must go on to apply the formulæ to centrifugal machines.

If it were possible to construct a centrifuge with an infinitely long radius of rotation, we could use precisely the same formulæ for centrifugal separation as for gravity subsidence. But, given a constant r.p.m., the force varies directly with the radius of rotation, and the force is greater at the periphery, 0, than at the surface, 1. In Fig. 4, let the distance from the center of rotation to the periphery be designated by R . The radius of rotation of any point, x , may be expressed by $R - x$. Therefore, we have

$$\begin{aligned} f_o &= \frac{R}{R-x}, \\ f_x &= f_o \frac{R-x}{R}, \end{aligned}$$

where f is the factor multiplying the acceleration of gravity. The centrifugal force, $f_x g$, at any point, x , is equal to a function of x involving the centrifugal force, $f_o g$, at the periphery.

The general expression for distribution in the case of centrifugal force is

$$\log_e \frac{c_o}{c_x} = mf_x g k x,$$

or

$$= m k f_o g x \left(\frac{R-x}{R} \right).$$

$$\text{Let } \beta = m k f_o g,$$

$$\text{and let } k_i = \int c_x dx = c_o \int e^{-\beta x \left(1 - \frac{x}{R}\right)} dx.$$

This function cannot be actually integrated by the ordinary calculus. But approximation by the prismoidal form yields a very nearly accurate result between 0 and 1.

$$k_i = \frac{c_o}{6} \left[1 + 4e^{-\beta \left(1 - \frac{5}{R}\right)} + e^{-\beta \left(1 - \frac{1}{R}\right)} \right].$$

In the special case of the centrifuge represented diagrammatically in Figs. 1 and 4, the value of R is 2, and the depth of liquid is 1 centimeter. The expression therefore becomes

$$k_i = \frac{c_o}{6} [1 + 4e^{-.375\beta} + e^{-.5\beta}];$$

$$c_o = k_i \left[\frac{6}{1 + 4e^{-.375\beta} + e^{-.5\beta}} \right];$$

$$c_x = c_o \left[e^{\beta x \left(\frac{x}{2} - 1 \right)} \right]$$

$$c_x = k_i \left[\frac{6e^{\beta x \left(\frac{x}{2} - 1 \right)}}{1 + 4e^{-.375\beta} + e^{-.5\beta}} \right].$$

This equation is identical in purpose with the simpler form derived for gravity subsidence. k_i represents concentration throughout the liquid before subsidence. It is seen that the factor essentially influencing centrifugal subsidence is

$$\beta = m k f_o g.$$

In the case of the particular centrifuge in mind, f_o is 40,000. Therefore

$$\beta = 4 \times 10^{23} r d.$$

Let us see what happens when we subject a 1 per cent dispersoid to such a force.

β	c_1	c_2	c_0
1	0.80	0.95	1.36
10	0.06	0.08	6.00
100	10^{-10}	10^{-10}	6.00

The results for equilibrium under centrifugal force are seen to be very similar to those for gravity subsidence. Here again we find that separation is good when $\beta = 10$ and practically perfect when $\beta = 100$.

It should be clearly understood that the formulæ given above are expressions of equilibrium. If a dispersoid whose particles are just visible to the ultra-microscope is subjected to a force of 40,000 times gravity, the particles will be thrown down, provided the force is applied for a sufficient time.

Computation of Time.—Many observations in the laboratory under widely varying conditions have led the writer to conclude that precisely the same time is required for each particle of a given dispersoid to move from its position of uniform distribution to the positions of equilibrium. But that this assumption must be correct is evident, not only from observation but from a study of the principles underlying the law of distribution. The particle at $x = 1$ will move with

FIG. 4

greater velocity and a longer distance than the particle at $x = 0.5$, but the time will be identical.

The centrifugal force at any point is

$$f_x g = f_0 g \left(1 - \frac{x}{2}\right).$$

The centrifugal force acting upon the particles represented by the concentration, k , can be expressed by

$$f_x g = k f_0 g \left(1 - \frac{x}{2}\right).$$

Earlier in this paper, it was pointed out that the only considerable force opposing gravity is osmotic pressure.

The osmotic pressure of one particle in unit volume, according to the kinetic theory, is equal to the reciprocal of the constant, k , that enters into our functions of x and β . When c_x represents a concentration by weight percentage, the number of particles in unit volume is

$$\frac{c_x}{m},$$

where m is the mass of one particle. The number of particles in the volume $(1-x)$ is

$$\frac{c_x}{m} (1-x).$$

The osmotic pressure, P , at any point, x , is therefore

$$P_x = \frac{c_x}{mk} (1-x).$$

Now

$$c_x = k_i \left[\frac{6e^{\beta x} \left(\frac{x}{2} - 1\right)}{1 + 4e^{-375\beta} + e^{-5\beta}} \right],$$

and if we let

$$\varphi(\beta) = \frac{1 + 4e^{-375\beta} + e^{-5\beta}}{6},$$

we can write

$$P_x = k_i \frac{e^{\beta x} \left(\frac{x}{2} - 1\right)}{mk \varphi(\beta)} (1-x),$$

and since

$$mk = \frac{f_0 g}{\beta},$$

we can write

$$P_x = f_0 g k_i \frac{e^{\beta x} \left(\frac{x}{2} - 1\right)}{\beta \varphi(\beta)} (1-x).$$

The actual force F_x exerted on the particles of a dispersoid can therefore be expressed by

$$F_x = k f_0 g \left[1 - \frac{x}{2} - (1-x) \frac{e^{\beta x} \left(\frac{x}{2} - 1\right)}{\beta \varphi(\beta)} \right].$$

When Stokes' law is applied to particles of given mass acted upon by the acceleration of gravity, it is necessary to put

$$\begin{aligned} f &= mg \\ &= \frac{4}{3} \pi r^3 d g. \end{aligned}$$

Thus, we have

$$U_0 = \frac{2r^2 dg}{9\eta},$$

or for the special case of the centrifuge

$$U_x = \frac{2r^2 dF_x}{9\eta},$$

$$U_x = \theta(\beta) \left[1 - \frac{x}{2} - (1-x) \frac{e^{\beta x} \left(\frac{x}{2} - 1\right)}{\beta \varphi(\beta)} \right],$$

where

$$\theta(\beta) = k f_0 g \frac{2r^2 d}{9\eta} - k f_0 g \frac{\beta}{18k\eta}.$$

Now velocity, by definition, is the distance traversed in unit time. The time required to traverse the distance $(1-x)$, must be equal to

$$\frac{1-x}{U_x}.$$

$$\text{Time } (1-x) = \frac{1-x}{1-x}$$

$$\theta(\beta) \left[1 - \frac{x}{2} - (1-x) \frac{e^{\beta x} \left(\frac{x}{2} - 1\right)}{\beta \varphi(\beta)} \right]$$

But, as we pointed out above, the time is not a function of the distance traversed. It is evident that the distance $(1-x)$ is a function of β , and since the distance to be traversed by any particle depends upon the factor defining the concentration, we may put

$$x = \varphi(\beta) = \frac{1 + 4e^{-375\beta} + e^{-5\beta}}{6}.$$

Substituting in the equation for time, we have

$$\text{Time} = \frac{1 - \varphi(\beta)}{1 - \varphi(\beta)}$$

$$\theta(\beta) \left[1 - \frac{\varphi(\beta)}{2} - (1 - \varphi(\beta)) \frac{e^{\beta \varphi(\beta)} \left(\frac{\varphi(\beta)}{2} - 1\right)}{\beta \varphi(\beta)} \right]$$

This expression gives the time required for particles to traverse from positions of uniform distribution to positions of equilibrium, in a centrifuge whose radius is 2 and whose depth of liquid is 1. The value is the same for particles of given mass and for liquids of the same value of viscosity.

The following tabulation shows the time,* according to this formula, required for separation of dispersoids whose dispersion media is water ($\eta = 0.01$ in c.g.s. units). The density of the particles is taken as 1, and the concentration, k_i , is 1 per cent.

Radius	β	$\theta(\beta)$	Time	
C_m				
10^{-8}	$0.1\mu\mu$	4×10^{-3}	8×10^{-6}	13 days
10^{-7}	$1.0\mu\mu$	4	8×10^{-6}	33 hours
10^{-6}	$10.0\mu\mu$	4×10^3	8×10^{-4}	18 minutes
10^{-5}	0.1μ	4×10^6	8×10^{-3}	11 seconds
10^{-4}	1.0μ	4×10^9	8×10^{-6}	.1 second
10^{-3}	10.0μ	4×10^{12}	8×10^{-1}	.001 second

It will be seen that when β is larger than 100, the time is about equal to $\frac{1}{\theta(\beta)}$ in seconds.

Some objections may be offered to the derivation of our equation for time. Whatever the merits of the case, our equation has two rather unusual characteristics, it is easy to use, and its results, as far as we have observed, will accord with every laboratory measurement.

Practical Considerations.—The great point of superiority of the continuous centrifuge over the non-continuous type is the possibility of handling practical volumes of liquid. When the volume is great, the liquid must pass quickly through the rotor and the time during which the centrifugal force can act on the dispersoid is limited. The time in each case is dependent upon the stationary capacity of the rotor. For instance, if we must pass 10 liters of liquid into a given rotor before the level is high enough to overflow (or discharge), it would seem that the time in minutes during which each unit of liquid remains in the rotor will be equal to the rate of flow in liters per minute divided by 10. As

*It must be remembered that these figures will apply only to the centrifuge exerting a force of 40,000 times gravity and having a radius of 2 centimeters. For any other force or diameter, the proper expressions can be easily derived from the general forms.

a matter of fact, the actual time will be less than this quotient by an interval depending upon the mechanical arrangements of feeding, discharge, etc. Naturally, for any commercial application, a continuous centrifugal will be practical only when it can handle certain required volumes per day. The sizes of particles removed under such restrictions of time will be definitely limited. The capacity of the high speed centrifugal rotor has been limited in practice by strength of materials, but the degree of centrifugal force exerted has not yet reached any such practical limit. It would therefore seem worth while to answer the question: Will any advantage be gained by applying a much greater centrifugal force?

From the tabulation below, it is easy to see a partial answer. These calculations are based on a viscosity of 1. Values of f_0 are taken from 10^2 to 10^7 .

r	10^2	10^3	10^4	4×10^4	10^5	10^6	10^7
100μ	0.5 sec.	5 sec.	50 sec.	12 sec.	5 sec.	50 sec.	5 sec.
10μ	50 sec.	8 min.	12 sec.	8 min.	11 hrs.	8 min.	8 min.
1μ	11 hrs.	11 hrs.	11 hrs.	20 min.	11 hrs.	11 hrs.	11 hrs.
0.1μ							
$10\mu\mu$							

The values of β for every size of particle with the corresponding centrifugal force shown here are so large that the separation will be complete in every case.

The highest degree of centrifugal force at present commercially applied is 40,000. The lowest practical rate of continuous flow represents in this case a maximum time of about twenty minutes. One per cent suspensions of particles of various densities in liquids of various viscosities can therefore be completely separated by this machine in continuous operation according to the following table:

Size of Particle		Viscosity.
$d = 1.00$	$1.0\mu\mu$	.0001
	$3.0\mu\mu$	.001
	$10.0\mu\mu$	.01
	$30.0\mu\mu$	.10
	0.1μ	1.00
	0.3μ	10.00
$d = 0.01$	$10.0\mu\mu$	.0001
	$30.0\mu\mu$	.001
	0.1μ	.01
	0.3μ	.10
	1.0μ	1.00
	3.0μ	10.00

Any continuous flow machine can be operated with small separate lots of liquid as an ordinary "bottle" centrifugal. In this way it is possible to remove even smaller particles than shown above.

The determining factors are seen to be viscosity and absolute density. The minimum size of particle is affected by both to the same extent, for we see from the approximate equation for time,

$$\text{time} = \frac{9\eta}{f_0 g k_1 2r^2 d'}$$

that

$$\frac{r_1}{r_2} = \frac{d_1}{d_2} = \frac{\eta_1}{\eta_2}$$

In practice, one will rarely meet with a case where the density of the medium and the density of the particle are the same to the second decimal place. When such an equality is approximated, it is well to bear in mind the fact that density increases with degree of dispersity. For instance, the density of a globule of water

$30\mu\mu$ in diameter is 0.5 per cent greater than that of water *en masse*.¹⁷ The density of gold in various forms has been determined¹⁸ as follows:

Molten and compressed.....	19.33
Colloid, ppt. by ferrous sulphate.....	20.71

The question has sometimes been raised as to whether viscosity, the measure of the internal friction of a liquid, can be truly the absolute measure of the resistance to the motion of a particle. One might expect the physical characteristics of the particle to be a potent factor. But it is believed that each colloid particle is enveloped by a permanent film of the dispersion medium, and that whenever the particle is moved, the film will be dragged along.

The accuracy of the figures given for the high power machine has been verified in a number of ways by experimental work. In some cases the value of β has been so small that separation could not be complete and the theoretical concentration of the dispersoid was computed from the equation for c_r . In cases where β was large, and the liquid was drawn off before a state of equilibrium (i.e., complete separation) had been reached, the concentration was computed from the approximate formula for velocity. When β is large the change in concentration is directly proportional to the time, whereas with a small value of β the concentration will vary as an exponential function of the time. In other words, the time required for the particle to move the first millimeter will be very much less than the time required to move the next millimeter.

One interesting fact, which has been confirmed in practice, is that the particles of a polydispersoid (containing particles of several degrees of dispersity) can be separated accurately in fractions by applying various degrees of force.

For instance, a serum containing finely divided fibrin and corpuscular debris of various degrees of dispersity was subjected to a force of about 1700 times gravity. After the force had been applied fifteen minutes, the serum was perfectly transparent to the naked eye. But a fine porcelain filter was immediately clogged, showing that many particles larger than one micron still remained. The liquid was then whirled again with the same force for two hours. No sedimentation could be seen, and the Berkfeld filtration was equally difficult. A portion of the original serum was now passed through the centrifuge, exerting 40,000 times gravity, in which the time of application was five minutes. The resulting liquid contained only a few particles as large as 0.5 micron and 50 liters could be passed through the filter before clogage.

An emulsion of crude oil and water was found by distillation to contain 9 per cent water. When diluted with gasoline and subjected to the force of 1700 times gravity, 0.9 per cent of water was separated in thirty minutes. The percentage recovery was not increased by extending the time to five hours. The same gasoline mixture was passed through the high power centrifugal at a rate that insured less than a minute for separation. The yield of water was 8.8 per cent.

These two examples might be multiplied indefinitely from the writer's experience. They show in a concrete manner that a separation that is impossible to secure by a lower degree of force, even though the time be extended far beyond the limits of practicability, can often be secured in a very short time by a more powerful machine.

The Centrifugal Separation of Solutes.—The experiment of Van Calcar and Lobry de Bruyn, mentioned earlier in this paper, in which three degrees of the salt

¹⁷"Handbook of Colloid Chemistry," Vo. Ostwald-Fischer, p. 12.
¹⁸G. Rose, Poggendorff's Ann., Vol. LXXIII, 1 (1848).

was crystallized out from a saturated Glauber's salt solution by whirling in a centrifuge, is very interesting in view of the theoretics developed above. With the comparatively low force applied, and the extremely small size of the particles, the value of β would be very small (about 10^{-4}). The condition of equilibrium of the molecules would therefore show an increase in concentration at the periphery of a very small fraction of a per cent. But this slight increase means *supersaturation*, and supersaturation has been described by P. P. Von Weimarn as a transition between the true molecular dispersoid and the colloid. The value of β would therefore become correspondingly greater, and toward the end of the period (five hours) the effect of agglomeration crystallization would be quite noticeable. This is, therefore, a somewhat more complex problem than a mere centrifugal separation.

The partial separation of certain gases should, according to our calculations, be within the range of possibility. With 40,000 times gravity, the value of β would be small and separation necessarily incomplete, but the time required to reach this state of equilibrium should be reasonably small on account of the very low viscosity. The continuous separation of gases has not yet been actually tried in practice on account of certain mechanical difficulties of separate discharge, but these difficulties will no doubt be overcome. Complete separations of gases cannot be accomplished by any force less than about one hundred million times gravity.

If a mixture of gasoline and kerosene is passed through the rotor exerting 40,000 times gravity, at the slowest practical rate the difference in concentration between the layers at the surface and at the periphery would be much too small for any analytical detection. If the mixture were held in the rotor for three weeks, an equilibrium would be established, but even then the difference in concentration would be in the fourth decimal place. A force of one million times gravity applied for several days should give a quite appreciable subsidence, but a complete separation would require a hundred million times the acceleration of gravity.

Recapitulation.—Particles of uniform size suspended in a liquid medium will settle by gravity when the product of their mass in grams by the constant 3×10^4 is as large as 10. When the product is less than 10, a partial subsidence will occur until an equilibrium is established.

The only considerable force opposing complete subsidence in this case is osmotic pressure. By the use of a law of distribution, which takes into account the opposing forces, it is possible to compute the concentration at any level when the system is at equilibrium.

When the conditions are such that a particle will not settle completely by gravity, it is possible to cause complete subsidence by the application of centrifugal force when the product of the mass in grams, the force in dynes, and the constant 3×10^9 is greater than 10. Here again a partial subsidence with the establishment of an equilibrium will occur when the product is less than 10.

The time required to establish this equilibrium can be computed from a modification of Stokes' law for velocity.

The highest commercial centrifugal force, 40,000 times gravity, can completely remove particles as small as the lower limit of ultra-microscopic observation, but such a separation will require thirty-three hours when the liquid medium is water. For less viscous media the time will be shortened. Smaller particles can never be separated by this force. Particles just too small to be retained by a fine porcelain filter can be removed in a few seconds.

Gases of different densities cannot be completely separated by any force less than about one hundred million times gravity. The same applies to true solutions. But gases should be partially separated by a much lower force within a reasonable time, whereas solutions in liquid media would require several weeks.

The Carbonization of Kelp for the Recovery of Potash

By J. W. Turrentine

The development of an American supply of potash for domestic industries is still unrealized, despite the fact that American resources in this commodity have been known for several years and numerous attempts on a commercial scale have been made to develop the various sources indicated. Efforts have been made to produce potash from feldspar, alunite, potassic brines and kelp. So far, the proper combination of character and accessibility of raw materials and feasibility of methods of handling has not been found that insures any adequate supply of potash for normal conditions of industry and market.

As the result of the antebellum experiments and the greatly stimulated efforts inaugurated since the beginning of the European war, it may be generalized that the giant kelps of the Pacific Coast still offer the best promise of supplying the proper conditions for the establishment of a domestic potash industry. Thus, they occur in sufficient quantity, they are accessible and the product, under normal conditions, may be delivered at the market—the Atlantic seaboard—at a charge for freight that is not prohibitive.

Notwithstanding the numerous experiments made at various times and along various lines looking to the establishment of proper methods for treating kelp, it yet remains to be shown what the costs will be for harvesting the material and ridding it of its high water content. The devices so far designed show great promise of the ultimate solution of the problem of cheap harvesting. This is a mechanical problem which safely may be trusted to American ingenuity.

The leaching of kelp in fresh water for the extraction of the potash salts on the laboratory scale has failed to produce promising results. The destruction or the alteration of the organic constituents of a mash of macerated kelp by fermentation, followed by coagulation of the jelly and filtration, has received some attention and may be susceptible of favorable development. The removal of water from the kelp by pressure methods shows less promise because of the gelatinous condition of kelp and the fact of the potash salts being held in solution in the plant jelly. The rotary kiln, found so adaptable and economical in other industries, has been applied with considerable, though not with unqualified, success, to the drying of kelp. Better results seem promised when the kiln is operated counter-currentwise and the drying is effected in stages. The solution of these problems is of prime importance, since any kelp industry must be based on harvesting, and until that operation is solved no industry can be developed; where ten to six units of the raw material to one of the dry is to be handled as in harvesting, the cost per unit quantity must be maintained at a minimum if that of the dry material is not to be prohibitively large.

With the aid of a climate such as that of southern California, of low rain-fall and that restricted to a few winter months, it should be possible to effect drying economically in the open air, if it were not for the me-

taneously in the open air, drying floors with plows for turning the material or elaborate racks with mechanical loading and unloading devices suggest themselves. With these disregarded, no methods of artificial drying seem so full of promise as that by means of the direct-heat rotary kiln.

These are matters familiar to those who have studied the problems connected with the potash-from-kelp industry. They are fundamental. And with their proper solution it seems possible that the kelp industry will be established; for dry kelp is a material which appears entirely adaptable to the potash trade. It is a vegetable powder, of a weight of about 50 lb. per cubic foot, which carries about 15 per cent potash (K₂O), and is comparable to the low-grade salts formerly imported in large quantity.

Since dry ground kelp contains 40 to 70 per cent organic matter, freight charges per unit weight of potash can be greatly reduced by the elimination of the organic matter; that is, by the preparation of high-grade potash salts. If, to accomplish this end, incinera-

¹Davis. "Uses of Peat," Bureau of Mines, Bul. 16, p. 110 (1911)

tion methods are adopted, the incineration must be effected at a temperature which does not induce fusion of the potash salts (750 deg. C.). Burning in the open air does not fulfill this condition. Destructive distillation suggests itself and seems to offer the desired solution. It already has been shown that valuable by-products are recoverable by destructive distillation when the latter is properly conducted.² Thus, from the distillation of 3000 g. kelp in a closed retort, the results summarized in Table II. were obtained.

The details of the experiments and observations are set forth in Table III.

²Turrentine, "A note on the Distillation of Kelp," orig. communication, 8th International Congr. Appl. Chem., 5, 313.

The composition of the gas obtained was shown to be as stated in Table IV.

The liquid portion of the distillate obtained when kelp is distilled destructively has been examined by Hoagland.³ His results are summarized in Table V., from which he concludes that "kelp distillates are of no practical importance." The recovery of ammonia from the evolved gases has not been studied.

The distillation of kelp is analogous, and in a sense similar, to that of coal for the production of illuminating gas and coke. As in the latter so in the former a continuous and automatic process, and one in which heat units are faithfully conserved, is desirable. Therefore, in designing an apparatus to accomplish this purpose

the continuous and automatic gas producers now in successful use in the gas and coke industry would be looked to to supply the apparatus of desired characteristics for the distillation of kelp.

There are on the market vertical gas producers which appear to possess features that would make them especially adaptable to the carbonization of kelp. Such a producer would consist essentially of a vertical retort, 25 ft. in height. This may be made in sections to be mounted upon each other and the sections be of such a graduated size that the retort is larger at bottom than at top, thus insuring an unrestricted movement of the charge in its course downward. At top, this may be joined directly with a magazine or charging hopper, from which the charge will pass automatically downward into the retort. Above, the charging hopper should connect through a gas-tight valve with a storage bin for the prepared charge. The latter may be filled by means of a conveyor. At its lower end the retort should be provided with an automatic discharge or extractor, which passes the coke at graded speed into a gas-tight discharging hopper beneath. Gas would pass out at the top of the retort, and be admitted through a tar trap into the main leading to the condenser house.

The retort should be inclosed in an envelope of brick provided with the proper arrangement of heating flues, regenerative devices and baffles. Heat would be generated in the space surrounding the retort. The air supplied for this combustion should be admitted through various passages constructed in the envelope in such a way that the

GAS PRODUCER FOR CARBONIZATION OF KELP

³J. Agri. Research, 4, 40 (1915).
⁴Loc. Cit.

air passing through will be heated in transit. Thus the loss of heat through radiation will be reduced to a small value. Likewise, the primary air, admitted at the bottom of the envelope, should be made to circulate around the bottom of the retort, thus cooling the charcoal contained therein and itself becoming pre-heated. The heat from the waste gases may be recovered by passing them through a tubular boiler situated near the bottom of the stack. Thus the temperature of the gases issuing from the envelope may be reduced to about 300 deg. Fahr.

Such apparatus has been tested for coal and has been found entirely successful with that material. The conditions imposed by the successful distillation of coal, it would appear, are much more severe than those imposed by the distillation of kelp. For the latter, as is evident from Table III, a temperature of 1000° F. is entirely adequate. Probably 750° of temperature would suffice, since considerable heat is evolved by the kelp in undergoing the exothermic reaction, apparently beginning at about 700° F. Coal becomes viscous and swells in coking, while kelp loses volume. Kelp probably would pass readily through a straight retort. It is possible that certain of the distillation products from kelp would condense in the upper portion of the retort, where a low temperature would be maintained, and by admixture with the pulverized kelp interfere with the flow of the charge; in which case the gases could be led out at a hotter part of the retort. In general, it may be said the most serious complications conceivably arising in the carbonization of kelp in the apparatus under discussion appear to be so slight that they readily could be overcome.

The charcoal obtained when kelp is distilled, containing the soluble salts, potassium and sodium chlorides, is porous and easily may be leached. By the application of well-known leaching methods a practically saturated solution of these salts and a charcoal freed therefrom may be obtained. The charcoal could be consumed in an auxiliary gas producer or it might be marketed locally for fuel. The gas evolved from the kelp during distillation, after treatment for the recovery of by-products, would be used for maintaining the temperature around the retort, for which it probably would be more than adequate; and any excess would be applicable to the evaporation of the solution of salts or as an auxiliary fuel in the operation of the kilns. The tar and oils recovered would be useful as fuels if no more profitable application could be found for them.

In short, the system would make possible the complete utilization of any fuels produced and heat units generated. The other by-products obtainable from the distillate could be recovered by methods already well understood, if further experimentation warranted. The large volume of water produced might make the recovery of methyl alcohol and acetic acid impracticable unless they were condensed fractionally. Finally, the crystallization of high-grade salts with the conservation of mother liquors, would make possible the recovery of iodine, for which, after all, there is a certain domestic market.

The cost of such apparatus complete and installed, as constructed for the carbonization of coal, is approximately \$50,000 for a daily capacity of 50 tons coal. This is inclusive of fireproof house. For kelp a cheaper construction would be adequate on account of the greatly reduced temperature maintained and the consequent lack of necessity for the use of high-grade refractory materials. Likewise, on account of the greater ease with which kelp could be carbonized, a greater capacity per retort would be possible with

a consequent reduction in the number of retorts necessary—a value to be determined by experimentation.

The operating expenses would be light. In gas producing plants of large capacity, one man per shift on the operating floor and two, working part time, on the discharging floor, are found to be adequate. The operation of such a plant is almost automatic. Additional expenses would be incurred for the operation of an elevator to deliver the material to be carbonized into the storage bins at the top, and to actuate the discharge rolls at the bottom. Other items to be considered are upkeep and interest on investment.

The principal economy to be expected is the reduction in freight rates, a reduction of from 50 per cent to 75 per cent per unit weight of potash. This item alone would justify the installation. The utilization of the combustible portion of the kelp for the generation of heat to assist in the desiccating operations of the plant would put to use those constituents to which no value would be attached in the market. And finally, other by-products, otherwise lost, would be recoverable if such were found to be justifiable by their value.

The History and Legal Phases of the Smoke Problem*

By Ligon Johnson

Only the acute phase of the smelter fume problem is new. The problem itself is older than the Christian era.

While both lead and copper were mined and crudely smelted some three thousand years ago it was not until the Roman occupation of the Iberian Peninsula and the British Isles, which occurred but shortly before the beginning of the Christian era, that there was any evidence of smelting operations on a scale sufficiently large to permit of a fume problem.

Around Huelva, Spain, are found more than 30,000,000 of tons of slag from lead smelting conducted there by the Romans. Pliny tells us that more than 20,000 slaves were employed in the Iberian mines. Extensive mining and smelting by the Romans in England and Wales were coincident with the Iberian proceedings.

These metallurgical operations were upon a sufficiently large scale to produce marked results both upon the surrounding country and the smelter workers, but, as these operations were those of a conqueror upon conquered soil, conducted by slaves, imperial Rome failed to recognize that such a thing as a smoke problem did or could arise, and whatever fume question there may have been at that time remained a question only to those who had no chance to answer any phase of it.

The smelting operations of the Romans extended over about 400 years and little is recorded of lead and copper smelting from that time until the sixteenth century. From the revival beginning at this period up to the present century the growth of smelting has been comparatively gradual. In Great Britain smelting was conducted almost wholly in localities where metallurgical operations were of paramount importance, and the communities which grew up in smelter localities were due to and dependent upon the mines and smelters. This fact had much to do with the comparative freedom of British smelting from burdensome fume litigation and legislation. To a lesser degree these conditions applied to the German operations, which, when coupled with the further fact that most

*A paper read at the Joint meeting of the New York sections of the American Institute of Mining Engineers and the American Electrochemical Society on January 26, 1917.

of the early German operations were to a greater or less degree fiscal workings of Prussia, Saxony and Brunswick-Hanover accounts for the early immunity of German smelters. Topographically and with relation to fertile farm lands, the locations of the British smelters were superior to the German, and ultimately a strong legislative barrier was erected around German operations, particularly in the case of new smelters and under new locations of old plants.

Nowadays German smelting is or at least, prior to war conditions, was under supervision of special officials in the nature of mining police and courts. Before construction of a smelter could be begun application for a permit had to be made, and this application accompanied by general data as to location, character, capacity, height of stack, character of ore to be treated and the like. Where a permit was once granted, it was not revocable, but notwithstanding the permit, if damage was done the smelter could be required to change its methods and to install such appliances as would, so far as possible, prevent injury. Where a permit was refused, no smelter could be built. The refusal of a permit by the Bergpolizei or mining police was not final, but an appeal could be had to the Berg Gericht or Mines Court and finally to the Ober Berg Gericht or Mines Court of Appeals, which was the tribunal of last resort. Incidentally, the Bergpolizei had inquisitorial or supervisor powers not only as to damage to vegetation but also as to the safety of the works and the life and health of the employees.

It is supposed by many that the British Alkali Act was aimed at the smelting industry. This is far from correct. The original acts were directed chiefly at the manufacture of soda, acids, and ammonia. In 1861 the House of Lords provided for an inquiry "into the injuries resulting from noxious vapors evolved from certain manufacturing processes, and into the state of the law relating thereto." While the investigation covered smelting as well as the other enterprises, the resulting act (the Alkali Act of 1863) covered only so-called alkali works and provided for the elimination of not less than 95 per cent of the hydrochloric acid produced in alkali processes. By an amendment of 1874 it was enacted that not more than 1/5 of a grain of acid should be contained in each cubic foot of gas escaping from the works.

The original act was made more comprehensive by amendments and revisions of 1874, 1881 and 1892, but outside of operations under the wet copper process and certain zinc processes it was not until 1906 that smelting generally was included, and, even then, no actual regulation was provided as the act so far as smelting was concerned merely declared that the inspectors under the act "may inquire whether in any works in which sulphide ores are calcined or smelted, means can be adopted at a reasonable expense from preventing the discharge from the furnaces or chimneys of such works into the atmosphere of any noxious or offensive gas evolved in such works, or for rendering such gas when discharged harmless or inoffensive."

No limitation was placed on smelting operations beyond inquiring as to the installation of such remedial methods or appliances as might be installed at a reasonable expense. There was no prohibition as to tonnage or fume strength, and the first report of the inspectors touching on smelting was in the forty-fourth annual report of the department for the year 1907, forty-five years after the passage of the original act, and this embodied no smelter regulations.

Fume controversies and the attendant litigation and legislation are of comparatively recent origin in the United States. Probably the first thing in the way of

legislation in this connection was the ordinance of Oakland, Cal., enacted in 1872, prohibiting the erection or maintenance of any smelter within the corporate limits of that city. Subsequent California legislation was enacted by Contra Costa County limiting fume strength and by the State providing for a smelter commission to investigate the effect of fumes liberated in smelter operations. Efforts were also made to prohibit by legislative enactment the elimination of stack gases containing more than two-tenths of 1 per cent sulphurous content. This proposed legislation, however, was defeated. There has been little legislation either by the States or municipalities of the United States.

Not until heap roasting of ores rich in sulphur was practised on an extensive scale was there any litigation of consequence in this country, and to the condition resulting from heap roasting may be charged no small amount of the prejudice by the farmers against smelters and belief by them of the complete destruction of vegetation, animals and soil vitality.

The basis of this prejudice and belief is easily apparent, even to this day, under a visit to Butte, Shasta County, California; Ducktown, Tenn., and other places where heap roasting was extensively practised.

Under heap roasting, strong fumes, in dense volume, were liberated directly on the surface of the earth. These fumes were heavier than air and cold, being practically of atmospheric temperature. They did not float off in the atmosphere but hugged the ground, rolling along in front of the wind in constant volume until absorbed by the soil and vegetation. There was little diffusion and the radius of fume influence gradually widened with the destruction of each successive barrier of vegetation.

The topography of the country surrounding the roast heaps was, almost without exception, sharply declivitous as the roasting operations were conducted in hilly and mountainous regions. The soils of the regions surrounding the smelter sites were coarse and grainy, requiring the binder of the roots of vegetation and humus to hold the soil particles together.

The destruction of plant life adjacent to heap roasting operations resulted not only in the loss of vegetable life above the soil but of the roots below, and, with every rain, the top soil was eroded until considerable areas were not only made wholly barren, but the top soil washed away and only the decomposing rocks and mica were left. In consequence, there was no soil in which vegetation could find a foothold, even when the fumes were no longer present. It was from this erosion that the belief of the killing of the soil first arose.

From what they could already see, the people around the smelters believe the smelter smoke to be the veritable breath of the Upas tree which destroyed all within its reach, and that this deadly agency was daily reaching farther and farther from the smelter and in and upon the homes and farms surrounding the smelter sites. Litigation was then not only threatened, but instituted. First, the farmers sued the Tennessee and Ducktown companies, and upon the failure of these suits the State of Georgia took up the cudgel. The farmers in Shasta County, California, brought suit against the plants at Kennett and Gorum; the Benicia residents and adjacent farmers sued the Selby smelter; the United States, by reason of the ownership of a forest reserve adjoining the Keswick plant, filed its bill against the Mountain Copper Company. Not long after this the Deer Lodge Valley farmers filed their suit against the Washoe Company at Anaconda, and Salt Lake Valley farmers began proceedings against the smelters operating in that valley. The epidemic of smelter litigation was under way.

With these suits developed the early so-called smoke experts. Most of them had been in the heap-roasting communities where the destruction of vegetation and soil erosion had followed the heap roasting. No definite knowledge of fume action was available, and the experts for both plaintiffs and defendants, in the absence of knowledge, began to form pet theories only to be met by pet theories of others directly at variance.

In the good old days of theory an expert could make a casual inspection, or examine a few cross-sections of leaves under a microscope, or make a few comparative tests for the sulphur contents of healthy and unhealthy plants and deliver an epic on what the fumes were or were not doing. The appearance of the country around the old roast heaps and early plants were too big a handicap for the smelters to overcome, and, with the notable exception of the Washoe litigation, in practically every case an injunction followed.

About the time of the institution of those suits the smelters began the abandonment of heap roasting and the development of present-day operations. In this development prior theories expounded by the then experts or testified in the smelter suits had considerable bearing. In one locality everyone was assured that the injury came wholly from the dust particles; in another, from the dust particles as the nucleus for minute drops of acid; in another, from sulphuric acid vapor, which could be seen as a white fume cloud, and practically everything was blamed more than the chief, if not the sole, offender, the SO_2 . In many cases the courts followed these theories in their decrees.

The first development went to long settling flues, smoke houses and dust chambers, cooling and slowing down gases, and taking out so far as possible the solids and vapors. At the Tennessee plants acid making was attempted.

In most of the litigation, under re-adjustment to conform with decrees entered or modifications of these decrees, which modifications as a rule were secured under very substantial cash payments to the farmers, the smelters secured a new lease on life. Several, however, such as the Balakalala plant in California, and the Highland Boy at Salt Lake were completely closed, and passed into history as smelters.

It is interesting to note that not only were the findings of fact in the different cases widely at variance but the conclusions of law in many instances directly in conflict, even in cases in different circuits of the United States courts. For instance, in California and Montana, the United States Court held that the court could consider the balancing of conveniences, that is, that the court, in determining whether or not an injunction would be granted, could weigh the damage which would be done under closing a smelter against the benefits the farmers would receive under an injunction. In the Federal Court in Utah a directly contrary holding was made. In neither law nor facts did the courts coincide.

Some little time was required to make the plant changes to conform with the theories of the experts adopted by the court or the farmers and still further time was required to demonstrate the effectiveness of the changes. Most of the theories failed to pan out and gradually a new crop of complaints and claims that the recent installations did not prevent the damage, began to grow. Some claimants were insistent. Further injunction proceedings were threatened. Plant managers, remembering the results of old litigation, sought to temporize, instead of ascertaining the real facts and meeting them squarely. Some tried to buy peace. Let me say just here that nothing in the Selby report is truer than the statement (page 14) that "the

policy that 'buys off' trouble, as the most expedient commercial method of abating it has been responsible for much of the smelter litigation of this country and the intense ill-feeling that unfortunately exists toward smelters in many smelter communities." It did not take long under this practice for the price of peace to rise to prohibitive figures and a new epidemic of litigation was threatened.

Going back a little beyond this second period of threatened litigation and before the storm clouds of it were yet clearly over the horizon, I think that I may say that the smoke problem was then considered by most plant managers as the least of their troubles. Little or no thought of study was given the question and when it was mentioned it was waved aside. The worst most of them feared was having to judiciously distribute a little peace money.

A number of the smelters, such as the Washoe, Mammoth, Bully Hill, the old Mountain Copper, the proposed Engles smelter and others were either in or adjacent to National Forest Reserves and numerous reports of damage, or threatened damage began to come to the Chief of the Forest Service and Land Office, which reports were in turn referred to the Department of Justice. I was at that time Special Assistant to the Attorney General and these reports were finally referred to me with instructions to prepare and file bills for injunction unless some satisfactory solution could be reached.

While it was probably unknown to the smelters generally at that time, it was never the intention of the Government to close any plant. What it sought was the immediate and serious consideration of the fume problem and active effort to correct harmful conditions where such existed. Only one suit was filed, and that was the suit against the Anaconda plant. In each of the other cases stipulations were entered providing for research work and the installation of the highest types of methods and appliances known to smelting science or else the abatement of the operations producing fumes in harmful quantities until such appliances had been installed and proven elsewhere, upon which they were to be installed at the smelter entering into the stipulation. In the Anaconda case the first scientific commission was agreed upon. We proposed that the smelter operate under the best type of methods and appliances known to science and commercially feasible at the plant and that a commission of John Hays Hammond, Dr. Ricketts and Dr. Holmes, Chief of the Bureau of Mines, be designated as a commission to investigate and prescribe what changes or installations should be made under the agreement.

It was not long after this that the threat of further litigation by the farmers became ominous, and, as I had completed my work with the Department of Justice, so far as smelting matters were concerned, I resigned to become what might be termed smoke or field counsel for the American Smelting & Refining Company.

The first urgent smoke matter in this connection was the Selby litigation, between Benecia residents and the Selby plant, which had been pending a dozen or more years. A flat injunction against the operation of the Selby plant had been granted, which injunction had been fought through the courts and finally approved by the Supreme Court. The case had been through the court of last resort and the injunction was to become effective in a month or six weeks time.

On examining the record I found this suit to be somewhat different from the average smelter suit. Very little claim or injury to vegetation was made. More stress was placed on injury to animals, but the chief ground of complaint was excessive discomfort and al-

leged nausea and illness produced by odors which the witnesses uniformly declared "to smell like rotten eggs" or the sulphur spring of an adjoining county which spring gave off quantities of sulphureted hydrogen.

An examination of the Selby plant disclosed that, regardless of what lead loss there might have been at other times, under changes made or under way no lead loss would occur and therefore no possible source of injury to animals could exist from the plant's operations and that there was no appreciable amount of sulphureted hydrogen given off by or generated in the smelter plant.

In the San Francisco region in the spring and summer months constant trade winds blow and these winds follow a direct line from the Selby smelter to Benicia where most of the complaining witnesses lived. Beyond the Selby plant but also directly in line of the trade winds over the Selby plant was a large oil refinery and asphalt works. The odors complained of by the witnesses all came in the early morning hours, and investigation disclosed that at the times involved in the testimony, the oil and asphalt stills were not capped and were poured at 3 or 4 o'clock in the morning. Here then was a source of odors, which odors traveled on the same winds that carried the Selby smoke. The smelter was guilty of none of the things upon which the injunction was based. Capping the oil and asphalt stills practically disposed of the unpleasant smells.

We notified the county attorney and commissioners of Salano County of these facts and stated that we proposed to decline to observe the injunction prohibiting the operation of the plant. This would mean additional long drawn out and expensive litigation. To obviate such a situation I proposed that the whole matter be referred to a commission of scientists of the highest type, the members to be agreed upon jointly, and the finding to be entered in the Selby case as the finding and decree in that case. Every access to the plant and full-facility for examination was to be given the commission. After many conferences an agreement along these lines was arrived at and the Selby Commission came into being. The members of the Commission were Dr. J. A. Holmes, Director of the Bureau of Mines; Dr. E. C. Franklin, then director of the Chemical Laboratories of the U. S. Public Health Service at Washington, and Ralph A. Gould, a chemical engineer of San Francisco. With the Selby commission came the first scientific research in smelter fumes along the lines of normal field conditions.

The examination of the Selby Commission extended over a period of about a year and a half and in the end clearly demonstrated that the smelter was doing none of the things found against it in the original decree; and the injunction was vacated.

Shortly after the time the Selby Commission began on its work the murmuring of discontented farmers became much louder. Crops had failed in many localities and wherever this crop shortage was in a smelter locality the smelter was blamed. This was particularly true where prior payments had been made to farmers. Peace was quoted at war prices.

As I before stated, this was very shortly after the Selby Commission began its work. Besides the research just beginning under the Selby Commission, there had not been in the United States or elsewhere, any experiments or research work with smelter fumes or SO₂ under natural field conditions. It is true that Haselhoff and Lindau, Von Schroeder and Reuss, E. Schroeter, Wieler and Hartleb, R. Hartig, Wisliucenus, Freitag, Sorauer, Ramaun, Gerlach, Schnitz-Dumont, Sabachnikoff, Haubner and Stockhardt in Europe, and Haywood and Pierce, and to a limited extent, Ebaugh and Talmage in the

United States had carried on some experiments, but in none of these were normal field conditions approximated. Some fumigations were carried on with leaves or twigs or small parts of plants in bell jars. Others were in hermetically sealed cabinets, or "smoke houses" so constructed that only abnormal conditions could result. The plants used were grown in pots or flats and were grown and kept under conditions that were not normal. The fumes introduced were from burning sulphur or sulphur and alcohol or else concentrated SO₂ let in from a tank or gas burette. The concentrations were unknown, absorption was not considered nor were chemical analysis of the air made. Environmental factors of temperature, humidity, light values, barometric pressure and time element of exposure were not considered. The plants used in the experiments were not grown to maturity nor were their food or crop values ascertained. As a matter of fact at the time these experiments were conducted, no quick and accurate method of air determination was even known to the experimenters. Even had these investigations been conducted with normal plants, under natural field conditions, the lack of knowledge or records of actual fume strengths reaching the plants and of the environmental factors involved, would have rendered the experiments practically valueless.

Some investigators of smelter regions placed much reliance on the sulphur content of plants collected in smelter neighborhoods notwithstanding the fact investigations in the Department of Agriculture have shown that the sulphur content of the same plant may vary as much as 3000 per cent at different times during the season and at the same period the content of the same species of plant will vary markedly, particularly under different percentages of soluble sulphur in the soils, which variance frequently occurs at short distances.

In other words, from farmers and experts the smelters were coming in for full blame for all crop failures and the managements actually did not know whether or not they were doing the damage. From my past experience, I knew that there were numerous plant injuries attributed to smelter smoke which even the most competent expert could not differentiate by mere observation or even microscopic study. Numberless diseases and injuries which were not caused by smelter smoke were pointed out as evidence of smoke damage.

No plant manager knew how much, if any of the damages attributed to the smelter was caused by it, and if there was damage, what operation of the smelter or element of waste had produced the damage. And, too, with the payment of damages communities of smoke farmers grew up. Their idea of farming was to let their places grow up in weeds and collect from the smelter the value of the maximum crops ever produced. Many smelters had paid damages for conditions which, it later developed, were not remotely attributable to smelter operations; but the farmers having once been paid insisted on continued payments. The price of peace was rising above the possible profits of smelter operations.

The time for theorizing had passed. It was necessary that the smelter managements know just what damage, if any, was being done, and if there was damage, how it was done and what was necessary to prevent such damage. Under my urgent recommendation, the first research department to ascertain all this was installed and it, in conjunction with the Selby Commission, blazed the way for real smoke engineering.

This research work involved chemistry, plant pathology, plant physiology, entomology, agronomy, dairy husbandry, and veterinary toxicology and meteorology.

You may wonder why all this was necessary just to find out whether or not the smelter was doing any of the things claimed and why one or two experts familiar

with the appearance of vegetation in smelter regions would not have sufficed.

We have to know first what smelter fume or parts of fume would do damage; how the injury could be caused; what conditions were or could be confused with smoke injury and finally, where damage was or could be done, what steps were necessary to obviate it.

This meant first extensive research work under normal field conditions to ascertain the effect of smelter eliminations upon vegetation and animal life. The time at hand is too short to go into a minute description of this research work. It will probably suffice to say that we found that dust and acid vapors were practically negligible quantities in the fume problem so far as vegetation was concerned. Where damage was done, this could be traced almost if not wholly to sulphur dioxide. The average vegetation can stand fifty times the strength of acid vapor that it can resist where the sulphur is administered in the form of SO_2 . In the average smelter fume the acid vapor is but a small fraction of the sulphur content, this latter being chiefly confined to sulphur dioxide.

It then became necessary to ascertain the relative resistance of the various plants to sulphur dioxide and the conditions under which injury occurred when the SO_2 was present in sufficient quantities to do damage.

To develop this fact it became necessary to know exactly how smelter fume acts upon plant life, how it obtains ingress to the plant structures and its effect after its absorption into the plant.

It may not be amiss just here to describe in a few words how this ingress comes about and the results which follow. In the beginning we found that only during the period the plant was in leaf could injury occur. Subjecting a plant to SO_2 or other fume while not in leaf produced no result. In most instances, and practically without exception in alkaline soils, we found that treating the soil in which the plants grew with sulphur or sulphuric acid, that is, dusting or spreading crude sulphur upon the soil or spraying the soil with acid, resulted in increased crop yield. Sulphur administered in this way was a benefit and not an injury. This conclusion was verified by independent experiments conducted at the University of California in Berkeley, at an experiment station in Oregon, and at the experimental farm of the Anaconda Copper Company.

The question then narrowed down to the effect of smelter fume through leaves and on leaf structure and to present this clearly it is necessary to describe the ordinary leaf and its functions.

All leaves under normal field conditions, in climates such as we have to deal with here, have an epidermis covering both the under and upper leaf structure. This epidermis is impervious to moisture and for all practical purposes, except where stomata or breathing pores occur, is also impervious to gases. These breathing pores are so small that considerable magnification under a microscope is necessary to see them at all. The stomatal openings are entirely too small to admit the minutest suspended water globules or particles of mist or vapor. The stomata at the leaf surface, are faced with two guard cells, that are also covered by practically impervious epidermis, which guard cells, under certain leaf functions, open or close the stomatic chamber. With the guard cells closed the leaf under ordinary conditions presents impervious surfaces to the elements. The inner content of the leaf, or the mesophyll, is composed of palisade cells, collecting cells and sponge parenchyma, in which, under this action of light, starch and sugar are formed and plant food manufactured and supplied the plant.

We next found that under conditions of absolute

closure of the stomata, the plant was a number of times more resistant to SO_2 than when the stomata were open. Under usual conditions the stomata forms the point of ingress of gas. It followed, therefore, that where an external condition brought about the closure of the stomata it brought about increased resistance, and we finally worked out four factors in chief in fume injury, where sulphur dioxide is present in strengths sufficient at any time to bleach plant life, these factors being light (the stomata are closed during darkness), humidity, temperature, and constant wind direction. The bearing of the latter comes from the fact that injury except from abnormally strong fumes does not come from mere fume puffs but from steady application of SO_2 for several hours. The other three factors bear upon stomatal opening.

After we had learned the strength of SO_2 necessary to produce markings upon plant life under field conditions, it became necessary to know whether or not SO_2 was present in such quantities in the field. It was also necessary to know accurately the wind constancy and direction, the limits of the smoke stream, temperature, humidity and general weather data. Complete installation of standard weather instruments, under the supervision of the local U. S. inspector, was made; and portable laboratories, that is laboratories set up in small automobiles which could follow the smoke stream as well as make general tests, were secured. This was in addition to the fixed air stations maintained. Under the method of air analysis devised by Mr. J. R. Marston and later refined by Mr. A. E. Wells, chief chemist for the Selby Commission, quick and accurate determinations of air samples were possible, and, more important still, these samples would be taken in a few seconds time and, in this way, the constancy or inconstancy of the SO_2 determined. For the smelter plants we cross-sectioned the several flues at the base of the outlet stacks and the stacks to afford analysis of their contents and installed self-recording thermometers at appropriate points in the flues and stacks for accurate and complete data as to gas temperatures.

With this knowledge the next step was to ascertain with scientific exactness the cause of crop failure or injury where the appearance of external conditions, and often even microscopic cross sections, were seemingly identical with the results of smoke injury, but where our other investigations had developed that smoke injury could not have occurred. There are many diseases, pathological condition and insect injuries, which, both externally and under the microscope, present an appearance practically identical with that of smoke injury. With the completion of this investigation, a survey of the so-called fume zone followed.

It is interesting to note that, in determining the injury of plants by disease, we can establish our diagnosis with scientific exactness not possible in the diagnosis of diseases of human beings or animals. We can establish our diagnosis beyond the possibility of doubt or question. This is done by what is known as the pure culture method. The unhealthy plant is pricked by a needle pointed instrument which in turn is dipped in a special and pure plant jelly and a culture of the disease organism is grown. The disease organism is isolated and reproduced. A healthy plant is then inoculated with this culture and after the disease develops comparison of appearance is made; a second culture is made from the inoculated plant and a second inoculation of a healthy plant follows, and in this way the disease organism is isolated, the disease and appearance reproduced and the diagnosis established beyond a reasonable doubt.

For insect causes, we find and collect the causative insect. As some insect colonies, although numbering

thousands, are so small that the individuals are only observable under very high-powered microscopes, and others work wholly out of sight and beneath the soil, it required a competent entomologist to handle this phase.

It will suffice to say here that we proceeded through the whole list of plant pathology, physiology, entomology, agronomy and dairy husbandry and veterinary toxicology with equal care and certainty. The time is too short to go into detailed explanation of the plan pursued under each.

One other agency in smoke determination has been established with relation to plant life and that is the evidence of so-called guide plants. There are certain plants, such as barley, which are especially susceptible to fume injury and will show bleaching long before the possibility of injury to other plants. Where the guide plants are unmarked, it is self-evident that the trouble with adjoining hardier plants is not smelter smoke.

In the work I have mentioned, we not only secured information valuable to the smelters, but we accomplished actual and beneficial conservation so far as the agricultural resources of the country are concerned.

Scientific farming is not yet widely practiced. Farming methods are often handed down from father to son. Year after year the same crops are planted, often on the same soil. This applies to farming generally and not merely to smelter communities.

In many places not only do the soils become impregnated with disease producing fungus and germs, but the result becomes so wide-spread that no healthy seed can be secured in the community. It often happens that disease conditions may largely be eradicated by proper treatment and planting of the seed and crop cultivation, but these facts as well as that the seed is diseased, are unknown to the farmer.

I recall a case where enormous claims for loss of potato crops were filed against a smelter. Upon investigation we found both the potatoes and the soil of the region highly infected with two of the most disastrous of potato troubles, rhizactonia and fusarium. A subsequent search of the seed stores in the community failed to disclose a single healthy sample of seed. Naturally the potato crops were failures. The sad part of it was that there was no need of this loss. Healthy seed procured elsewhere and planted in soil where potatoes had not been grown for several years, would have given the old time record crops, and proper treatment of the local seed would have produced infinitely larger returns.

Most of the diseases and insect conditions of agricultural communities are largely preventable and for those that are not, steps may be taken to greatly reduce the harmful effect. Much of the troubles can be directly pointed out to the farmer, and the means of eradicating or lessening these troubles can be shown him. This, of course, involves the demonstration that the unhealthy crop conditions are not attributable to the smelter.

The farmer who follows the suggestions for eradicating unhealthy conditions soon finds his crops exceeding those of his neighbors who have failed to observe the same precautions. In this way, gradually it is true, the influences of the smelter's experts is felt, a friendlier feeling is engendered, agricultural conditions are improved and actual conservation accomplished.

This brings us down to one final theory which in some places is still firmly entrenched and threatens possible trouble. I refer to visual clearance and the belief that anything seen coming from the smelter stack should be labeled with a skull and cross bones. Our investigations showed that the visible fume was little to be

feared as an actual instrument of damage to vegetation. Under former operations where a good part of the lead content of the ore was blown up the stack and where heavy arsenic fumes were given off, this metallic loss had some connection with certain animal troubles, but had little effect on vegetation. Where this character of loss was not involved, the visible fume was and is chiefly dangerous from the psychological point of view. By this I mean that most farmers (and many will be honest in their belief) will assert, so long as there are visible stack eliminations, that every crop failure is due to the smelter fumes. Therefore, to meet this, it will be advantageous to obtain the greatest possible clearance up to the point—and I want to stress this especially—where the efforts to secure visual clearance renders the smelter operations more liable to do actual damage. Beyond this point it is better to try to educate the farmer and get rid of the belief. Just because a farmer sees dense volumes of soft coal smoke pouring from the stacks of manufacturing plants, business houses, engines and the like, he feels no uneasiness about his crop. There is little if any more danger to crops in the visible smelter smoke. And, too, even where the belief of damage is deep seated, mere belief can be met by facts, but actual damage cannot be dodged because the smelter management seeks to meet some psychological condition; for mere belief won't last long in the face of actual damage.

Get clearance first for actual recoveries, and loss of toxic solids, and next, so far as possible, to meet any physiological conditions, but do not place visual clearance above the likelihood of actual damage.

Our investigation and the temperature curves we have worked out have shown us that where there is fume injury the answer to the problem is in hot gases, gas dilution, and high stacks. Anything that cools or slows down the gases or results in their liberation at low altitudes invites, to say the least, the probability of actual damage. Promising a community complete visual clearance or encouraging the belief that visual clearance means impossibility of damage is borrowing trouble for the future, for such a clearance, unless I am mistaken, means low gas temperatures.

These smoke problems are bringing to the front a new specialist, the smoke engineer. The far-sighted smelter management, under existing conditions, for all new construction, and even alterations and additions to old plants, will find this new expert a necessity rather than a luxury. The best way to take care of trouble is, not to stop it after it has started, but to prevent its starting. Many of the smelters realize this and those that do, in the matter of fume problem, welcome the coming of the smoke engineer and specialist.

Spring Meeting of American Chemical Society

The condensed general program of the spring meeting of the American Chemical Society, to be held in Kansas City, Mo., April 10-14, is as follows:

Tuesday night, April 10—Council meeting.

Wednesday morning, April 11—Opening session.

Wednesday afternoon, April 11—Opening session, continued, or section meetings.

Wednesday night, April 11—Smoker.

Thursday morning, April 12—Section meetings.

Thursday afternoon, April 12—Section meetings.

Thursday night, April 12—Banquet, or open.

Friday morning, April 13—Section meetings.

Friday afternoon, April 13—Excursions.

Friday night, April 13—Banquet, or open.

Saturday morning, April 14—Excursions.

Potash, as a Byproduct from the Blast Furnace*

By R. J. Wysor

Since the outbreak of the European war, few problems of raw-material supply have commanded more nation-wide attention than potash. It is well known that before the war the domestic production of potash was an insignificant percentage of the imports. The average annual importation of raw potash salts for several years prior to 1914 was slightly over 300,000 net tons, and of other potash manure salts about 700,000 tons. The sudden and almost total cessation of these imports created a unique and stringent situation. Methods of recovering potash from feldspar and other native mineral sources, and reclamation from hitherto waste products, have received a marked impetus. Soaring prices have been a keen incentive to research and industrial development.

Although several brief articles concerning the possibilities of potash recovery have appeared in recent trade journals, it still may be a matter of surprise to the average technical mind that potash might be reclaimed as a profitable byproduct in the manufacture of pig iron. At the present time it may be of special interest to present some data, largely of a technical nature, on this subject.

A fairly thorough search of the literature reveals a number of articles concerning salts of the alkali metals in the blast furnace. Many of them deal with the theoretical rôle of alkali cyanides in the furnace. Several discuss the probable effect of the alkalies on the furnace brickwork. Two or three ambitious patents have been granted for reclaiming potash or other products from blast-furnace gas. However, we have heard nothing further as to the practical application of these patents. Little literature of importance has appeared during the last 10 years concerning alkalies in blast-furnace practice, and I have discovered no record whatsoever as to the actual sale or commercial disposal of flue dust for its potash content until this was inaugurated in our plant at Bethlehem.

About 4 years ago, in the course of investigating blast-furnace stove efficiencies, I analyzed the fine, yellowish fume of which a considerable quantity was removed from the bottom of the stove checkerwork. The sample was found to contain, among other constituents, about 15 per cent water-soluble potash, which was somewhat surprising. This induced an investigation, which showed that considerable quantities of this material, hitherto a waste product, could be recovered from our stoves and gas-fired boiler settings. A search for a market was made without immediately satisfactory results. One fertilizer dealer claimed that the alumina content was too high. Others wished to make practical tests, and we furnished large samples for a full season's demonstration, satisfactory results being reported. But the pre-war-time prices offered hardly seemed to justify the trouble of reclaiming the dust.

With the beginning of the war and the subsequent spectacular rise in the potash market, conditions were changed. Knowing just what dust to recover, reclamation was immediately commenced, a satisfactory contract was negotiated, and this company has been disposing of the dust at a good profit ever since.

OCCURRENCE OF ALKALIES IN RAW MATERIALS

Potash doubtless occurs almost entirely in some form of feldspar or clay in all blast furnace raw materials.

*Abstract of a paper to be presented at the New York meeting, February, 1917, of the American Institute of Mining Engineers. The author is superintendent of blast furnaces at the Bethlehem Steel Company.

At Bethlehem we receive ores from many quarters of the globe, and an attempt was made to discover whether the relative percentages of alkalies in the various ores bear any special relation to the source, mineralogical nature, or to the silica and alumina contents of these ores. No striking relation was discovered, except that the manganese ores, from widely separated sources, were found to contain relatively high percentages of potash as compared to most iron ores. Iron ores of this country, including those of the South, containing upward of 1 per cent potash, or over, seem to be restricted to small areas.

The percentage of potash in different varieties of limestone and dolomite used as flux varies greatly, largely on account of intermixed clay, and may be surprisingly high. Per unit weight, the potash content of our flux charge at Bethlehem is considerably higher than in either the average ore or coke charge.

Few data are available on the alkali content of coke from different localities. Various standard Connells-ville cokes which we have examined have shown a much lower alkali content than our local byproduct coke made from West Virginia coals.

It may be a matter of some surprise to note that, with one exception, the soda contents of all the iron ores, the coke and the flux, subsequently listed, are much higher than the potash contents.

In the course of this investigation, samples of slag and flue dust from all of our Bethlehem furnaces were collected continuously over a period of 4 weeks during June and July, 1916, and analyzed for the alkalies.

The ratio of potash to soda is considerably higher in the coke than in the ore and stone. For each ton of pig iron produced, nearly 60 lb. of the alkali oxides are charged, constituents which certainly are of considerable importance in the working of the furnace, yet of which relatively little cognizance has been taken in the past.

However, due largely to the relatively high percentage of alkalies in our fuel and flux, and on account of the considerable quantity of alkali-bearing flue dust removed, it is my opinion that more potash and soda are charged into our blast furnaces, per unit of iron produced, than in any other large plant in this country.

ACTION OF ALKALIES WITHIN THE FURNACE

It is probable that a considerable part of the potash and soda charged into a blast furnace is evolved from the top by direct volatilization or heat decomposition, though alteration by chemical reaction of the alkaline salts or compounds liberated may occur before they have left the furnace. It is certain that a large part of the alkalies are carried down into the hotter zones of the furnace and are converted into cyanides by reaction with red hot carbon. Some investigators have attributed an appreciable part of their ore reduction to the action of cyanides, inferring that after being oxidized and driven to the cooler upper portion of the furnace they condense and are again carried down into the reducing zone. Whatever the action, it is self-evident that eventually the same amount of alkalies must be carried out of a furnace that is charged, and this takes place through the following avenues of escape:

1. *In Chemical Combination in the Slag.*—The literature is almost barren with reference to the presence of alkalies in blast-furnace slag. On account of the readiness with which the compounds of these metals are sublimed and carried out of the furnace with the gas, it might be inferred that only a negligible proportion would be found in the slag. This is far from the truth. Average samples from each of six furnaces in

operation for two bi-weekly periods were carefully analyzed for potash and soda.

The calculated weight of slag produced during this period was about 0.52 ton per ton of pig iron produced, which would account for a loss of alkalis as follows:

	Pounds	Per Cent of Total Charged
Average potash in slag per ton pig.....	4.5	20
Average soda in slag per ton pig.....	6.3	17

The percentage loss of the two alkalis in the slag is seen to be about the same, being somewhat greater in the case of potash.

2. *As Cyanide or Other Volatile or Inflammable Compound through the Iron and Cinder Notches.*—Part of the fume arising from the molten iron, and especially from the slag running from the furnace, is undoubtedly alkali compounds. I have often noticed a peculiar lavender or violet flame around the iron and cinder notches during casting or flushing, which I believe is due to some alkali salt or salts burning. The fume arising from the iron and cinder runners certainly contains a considerable percentage of alkalis.

3. *By Liquid Evaporation or Decomposition from Gas Around the Tuyères, Coolers, Mantel and Cooling Plates.*—Occasionally while removing a tuyère or cooler, a stream of liquid "cyanide," resembling water, will run out of the furnace, or can be seen exuding from the lining.

When cooling plates above the mantel burn out, due to the failure of the water supply, and a little gassing has commenced, beautiful white and yellow or yellowish-red crystals often build up around the apertures.

Liquid material sometimes also exudes from around the mantel plates and solidifies in heavy columns or stalactitic masses on the shell. This substance, containing some cyanides, is highly deliquescent.

4. *By Combination with the Brickwork or as an Accretion in the Form of Cyanide, Etc., and Removal when the Furnace is Blown Out.*—This is, of course, a relatively small but very interesting part of the alkalis charged during a campaign. Several authors have suggested that destruction of brickwork in certain stacks, particularly in the middle and upper zones, was due to action of alkalis. However, so far as chemical action is concerned, rather more importance has been attributed to reaction between carbon monoxide and iron oxide spots in the brickwork, with subsequent disruption of the brick mass. The destruction of linings is doubtless hastened somewhat in furnaces in which the burdens are relatively rich in alkalis.

The average sample of the hearth brick used in one furnace lining at Bethlehem by careful analysis showed a total alkali content of 1.60 per cent. After blowing out, a sample was secured of a number of these brick near the bottom of the hearth, appreciably discolored when broken, which showed a total alkali content of 3.36 per cent. Higher up in the lining the alkali enrichment is greater. Samples of pure white, mixed cyanides, etc., have been recovered in various plants from protected crevices in the brickwork, around the boshes after furnace campaigns, and a great deal more would be found if the contents of the stack could be removed dry.

The presence of ammonia around furnaces directly after being blown out is, of course, well known. Sometimes enormous quantities are evolved, the odor being apparent until the entire lining is removed and the hearth cleaned out. The chief source of ammonia gas is undoubtedly the alkali cyanides and ammonium chloride which decompose in the hot water or water vapor introduced to cool down the furnace. In passing, it is

interesting to recall that a very small part of the cyanide produced in a furnace is fixed and carried down into the salamander in the form of the peculiar compound, titanium cyano-nitride. The excess accumulation of alkalis in the brickwork, or in salt deposits in a furnace lining after a campaign, may literally amount to several tons.

5. *By Evolution in the Gas.*—The heavy flue dust which is carried out of the top of the furnace by the gas current, of course, contains approximately its normal percentage of alkalis. The finer portions of ore, stone and coke dust doubtless average somewhat higher in alkali content than the entire materials as charged. All the remaining potash and soda in the burden, not previously accounted for, is sublimed and passes out in the form of various salts or compounds as a fine fume.

Various investigators have studied blast-furnace flue dust with special reference to its potash content, but almost entirely from a scientific standpoint. It is true that at least one American and one foreign patent have been issued for the recovery of potash in flue dust, but no evidence has been found that any practical application has thus far been made. And, so far as can be ascertained, the first commercial disposition of the flue dust as a fertilizer was made by us at Bethlehem somewhat more than two years ago.

The progress of the alkalis in our practice will now be traced from the furnace top, through the gas mains, washers, stoves, boilers and stacks.

ALKALIES IN DRY DUST BETWEEN FURNACE AND WASHER

Besides the dust carried out by the relatively small amount of gas escaping from the furnace top, and the insignificant quantity permanently deposited along the mains, all the dust under the above heading is removed from the dust catcher. Representative bi-weekly samples of the dust-catcher flue dust were taken over the same period during which the slag samples were secured and analyzed, showing the following averages:

	Total K ₂ O Na ₂ O	Water Soluble K ₂ O Na ₂ O
Average for all furnaces, first period.....	0.53 1.16	0.31 0.30
Average for all furnaces, second period.....	0.70 1.42	0.25 0.20
Average for all furnaces, both periods.....	0.61 1.29	0.28 0.25
Ratio average total potash to average total soda.....	1:2.1	
Ratio average water-sol. potash to average water-sol. soda.....	1:0.9	
Ratio average water-sol. potash to average total potash.....	1:2.2	
Ratio average water-sol. soda to average total soda.....	1:5.2	

A much greater percentage of the total potash than of soda is present in a water-soluble condition.

The entire absence of cyanides in this dust, and even in concentrated alkaline samples, recovered further along in the gas system, furnishes further corroboration of the fact that in normal operation practically no cyanide is carried in the gas current from the furnace top. That it may be an occasional constituent of flue dust, because of abnormal furnace conditions, is evidenced by several records at hand.

Tests made at different times show that our dust catchers remove an average of about 100 lb. of dust per ton of pig iron produced. Using the average percentage of alkalis in flue dust for the four weeks, we find:

	Pounds	Per Cent of Total Charged
Average potash in flue dust from dust catcher per ton of pig.....	0.6	1.8
Average soda in flue dust from dust catcher per ton of pig.....	1.3	2.3

EFFECT OF PRIMARY WASHERS ON ALKALIES IN DUST

At Bethlehem we have in service a type of tower spray washer, in common use in this country. All of the gas for stoves and boilers, as well as for gas engines, is

washed, except from one furnace. Naturally, it would be thought that practically all of the alkaline material in the dust, most of it readily soluble in water, would be removed in the wet washers. The bulk of it is washed out, but it is a remarkable fact that much of the water-soluble alkalis, remains in the gas current after leaving the washers. Calculations based on alkalis charged into the furnaces, lost in the slag, dust catcher, stack gases, etc., and recovered from the stoves and boiler settings, indicate that about 21 per cent of the total potash (apparently only about 5 per cent of the soda) entering the primary washers, passes through them. The explanation for this fact is that the particles of fume are in such an exceedingly fine state of division that they escape contact with the relatively large drops of water. In my opinion, any washer which will successfully clean blast-furnace gas rich in this fume must employ spray nozzles or other devices which will discharge water in a fine mist, thus insuring intimacy of contact between dust and water particles. Our washers at present perform the function of selective precipitation, eliminating the relatively coarse and heavy iron ore and coke particles, while delivering the lighter particles of dust and fume into the primary clean gas mains.

ALKALIES IN DIRT FROM PRIMARY CLEAN GAS MAINS

The mains carrying gas from the primary washers to stoves, boilers and secondary gas-cleaning plant accumulate dirt or mud gradually, and are washed out at intervals of every two or three months. This dirt is black when wet but after being dried is dark gray, and after the fine particles of coke dust are burned out, it is of a light-gray or reddish-white color. Sometimes drippings from a clean-out door along a gas main will form beautiful long stalactites. This material is in general appearance similar to the stalactites mentioned as exuding from the furnace shell. A typical sample was found to have the following proximate composition: SiO_2 , 0.28 per cent; $\text{Fe}_2\text{O}_3 + \text{Al}_2\text{O}_3$, 0.68; CaO , trace; MgO , 0.25; K_2O , 44.63; Na_2O , 7.13; Cl , 37.22; CO_2 , 7.78; CN , trace; NH_3 , none. The almost utter absence of cyanide in this concentrated alkaline material is worthy of note.

ALKALINE DUST IN STOVES AND BOILER SETTINGS

The dark, wet dirt carried into the stoves, which at our plant are of the three-pass type, is dead burned, of course, the combustible or volatile constituents, etc., being expelled. The residue, in the form of an impalpable powder, collects to some extent in the bottom of the combustion chambers, a relatively large amount gathers in the bottom of the second and third pass checkers while the largest portion is carried out in the stack gases.

In the combustion chambers the dust frits together in friable masses. The accumulation is not great, the wells being cleaned out at intervals of about two months. However, the action on the brickwork is serious. All over the inner surface of the combustion-chamber walls, the lower surface of the dome, and the second pass checkers for a depth of several feet, a deep-green glaze is formed, or the brickwork is honeycombed. Along the fire-clay joints between the brick, the action is especially marked. Stove brick of a high silica content invariably glaze or slag, whereas those with a lower percentage of silica are more readily honeycombed or excoriated by the alkaline fume.

The thermal efficiency of the stoves is reduced, of course, by this glazing, erosive and honeycombing action, though repairs seldom have to be made during a furnace campaign.

The fine, light-colored dust, which accumulates in the

bottom of the second and third passes, is the material of commercial interest to us. It is cleaned out at intervals of three or four months. A typical pile of this dust freshly removed through one of the stove clean-out doors is shown in Fig. 1.

In the boiler houses the dust accumulates and is recovered every few days from the combustion chambers, from the passes and occasionally from the horizontal flues leading to the stacks. It becomes increasingly fine and richer in potash in its progress. The boiler tubes, of course, become coated with the dust and must be blown off with a steam or air lance.

The white fume continuously issuing from the top of the stove and boiler-house stacks is approximately of the same composition as that reclaimed in the last passes.

PROPERTIES AND QUANTITY OF ALKALINE DUST RECOVERED FOR SALE

As previously indicated, the dust recovered from the combustion chambers and stoves and boilers is a light, friable sinter, whereas the larger amount reclaimed from the passes and flues is in an exceedingly fine state of division. When drawn out of the stoves or boiler settings hot, it runs almost like quicksilver, but it absorbs a certain amount of water readily, and becomes somewhat clammy and heavy.

Sieve tests were attempted. By careful sifting, it was found that all of the alkaline dust would pass a 300-mesh sieve. It is a true fume. The small residues remaining on the various sieves, when examined under a magnifying glass, were found to be chiefly eroded brickwork.

Specific-gravity tests, also, cannot be made with accuracy. The lightest dust, without compression, will run well below 0.50 specific gravity. Samples taken from the checkerwork of five different stoves, and showing potash contents of 10 to 14 per cent, when tramped down gently in large glass measuring cylinders, showed the following varying densities: 0.68, 0.69, 0.73, 0.89, 0.96.

Knowing the exceedingly fine state of division and smooth, spherical nature of the ultimate particles in this fine fume, there is little cause for wonder that so much of it passes through a creditable wet washer untouched.

The water-soluble potash content of the dry, ignited dust, recovered from the stoves and boilers, having previously passed through the wet washers, will vary from about 5 to 20 per cent. Our practice has been to store the material in a large bin, capable of holding two or three carloads. The commercial recovery, begun in

FIG. 1—PILE OF DUST FROM STOVE

1914, was not thoroughly systematized until the ensuing spring. Thirty-six carloads, containing 1,073.5 tons with 106.3 tons of water-soluble potash, of alkaline dust shipped in the period of fifteen months, April 1, 1915, to July 1, 1916. This represents all the dust removed from stoves and boilers serving four 500-ton furnaces, which could be recovered in normal operation, without special effort. Instead of being dumped into a dirt car, the dust was simply emptied into a central bin. A number of other carloads of lower-grade material, contaminated by flue dust from unwashed gas, were also shipped from the other furnaces, but are not included in the above amount.

No readily volatile constituents, such as may occur in the unignited dust, of course, are to be found after roasting.

In general, the ratio of water-soluble to total potash is higher than in the case of soda.

The preponderance of both total and water-soluble potash over the corresponding soda determinations is impressive, showing the much greater removal of the latter in the wet washers, or its greater volatility, in which case it would be carried out of the stacks in greater quantity.

If we assume that the total soda content in the stove and boiler dust averages 40 per cent of the total potash content, and the water-soluble potash 80 per cent of the total potash, as appears reasonable from the foregoing analyses, then the total alkalis recovered in the fertilizer material in the above period is found to be:

Total potash	118 gross tons
Total soda	47 gross tons

Calculating on the basis of pig iron produced in the above fifteen-month period, the alkalis recovered in terms of total charged are as follows:

	Per Ton Pig. Pounds	Per Cent of Total Charged
Total potash recovered in fertilizer material 0.3	0.3	1.3
Total soda recovered in fertilizer material.. 0.1	0.1	0.3

The amount of potash recovered, though of considerable tonnage and value, is an insignificant percentage of the total charged.

At furnace plants using burdens rich in potash where the gas is unwashed, a considerable recovery still can be effected, though some precautions must be taken to avoid the coarser, raw flue dust. Several other furnace plants in the East, acting upon our suggestion, made directly or indirectly, have been recovering potash-bearing flue dust during the last year and a half.

ALKALINE DUST ESCAPING FROM STOVE AND BOILER-HOUSE STACKS

Some idea of the relative amount of alkalis discharged per unit value of gas from blast-furnace stove and boiler stacks may be gained by observing the color and depth of the fume. Dirty gas, of course, will obscure greatly the fine, white, alkaline fume. In Western practice, with washed gas, the escaping stack gases show a thin, white color. In our practice the stack fume is much heavier. At the plants in the Lebanon district, using Cornwall ore, the fume is relatively very dense.

About two years ago we made a series of tests, extending over a period of about a week, to determine the approximate amount of potash lost through our boiler-house stacks. The average results on the two largest stacks were as follows:

Average amount of dust per cubic foot, flue gas (62 deg. and 30 sec.), grains	0.12
Average percentage water-soluble K ₂ O in this dust	14.70
Average percentage total	18.60

Knowing the average volume of flue gas discharged, and the average volume of fuel gas consumed by the boiler houses, and produced by the furnaces, we can calculate roughly the weight of potash lost through the boiler-house stacks per ton of pig iron.

No actual tests have been made on potash losses from the stove stacks, but they should be slightly less per unit volume of fuel gas burned on account of the greater baffling action of the stove brickwork. We will assume these losses per unit volume of fuel gas to be 90 per cent as great as from the boiler-house stacks. The soda-potash ratios will be assumed to be the same as in the average stove dust.

	Per Ton Pig. Pounds	Per Cent of Total Charged
Total potash lost in boiler-house and stove-stack gases	2.6	11.2
Water-sol. potash lost in boiler-house and stove-stack gases	2.2	..
Total soda lost in boiler-house and stove-stack gases	1.1	2.8

ALKALIES LOST IN SECONDARY WET WASHER

A considerable percentage of the primary cleaned gas at Bethlehem is further cleaned in Theisen scrubbers for gas-engine use. Practically all of the fine dirt is thus removed, the small amount passing through the fine gas main and into the combustion chambers of the engines, having practically no cutting or scouring action, even when as much as 0.03 grain per cubic foot of gas is present. Samples of this dust, recovered near the engines, were of a smooth talcy consistency. The composition is similar to the finest stove dust.

The amount of alkalis recovered in the secondary scrubbers, per unit volume of gas, is practically the same as the sum of the alkalis precipitated in the stoves (or boiler passes) and escaping through the stacks. Knowing the gas-engine consumption of fuel gas, the alkalis removed in the wash water, calculated on the same basis as for the stoves and boilers, is readily found to be as follows:

	Per Ton Pig. Pounds	Per Cent of Total Charged
Total potash lost in secondary scrubbers.. 0.5	0.5	2.2
Total soda lost in secondary scrubbers.... 0.2	0.2	0.6

BALANCE SHEET FOR ALKALIES CHARGED, REMOVED AND LOST

Bearing in mind the extremely delicate nature of the problem, and the necessity for including a number of estimates, I will endeavor to summarize a rough balance sheet for alkalis, charged and produced in our average blast-furnace practice. Further, it will be remembered that this balance sheet is approximately representative of our local conditions only.

Apparently there is a greater loss of soda than of potash in the primary washer. This may be due to the greater solubility of the sodium salts, or to the larger size or possibly to the difference in contour of the fume particles of sodium compounds.

METHODS FOR FURTHER RECOVERY OF POTASH

In our present gas-cleaning practice, it appears that there is a loss in the primary washers alone of over half of the total potash charged, or about 12 lb. per ton of pig iron produced, though, as mentioned later, this amount is probably a little high. The amount recovered, while appreciable, and representing almost clear profit, is seen to be an insignificant part of the total, less than 1/2 per cent. Potash lost in the slag, around the shell and from the top of the furnace, for all practical purposes, is lost beyond recovery. The greater part of the alkali content of the flue dust removed from the dust catchers could be recovered by leaching in water,

TABLE VI—BALANCE SHEET FOR ALKALIES CHARGED, REMOVED AND LOST

	POTASH (K ₂ O)		SODA (Na ₂ O)	
	Pounds per Ton Pig Iron Produced	Per Cent Total Charged	Pounds per Ton Total Produced	Per Cent Total Charged
Total charged.....	22.4		35.6	
Lost in slag.....	4.5	20.0	6.3	17.0
Lost in fume, etc., from iron and cinder notches, and shell (est. 10 per cent of slag loss).....	0.4	2.0	0.6	1.7
Lost in gases from top of furnace (est. 5 per cent total gas losses).....	0.9	3.9	1.4	4.1
Lost by combination with brick-work of furnace, stoves, etc.,.....	negligible		negligible	
Recovered in dust-catcher dust.....	0.6	2.7	1.3	3.6
Lost in primary washers (est. by difference).....	12.5	55.9	24.6	69.5
Lost in secondary washers.....	0.5	2.2	0.2	0.6
Recovered in stove and boiler passes.....	0.3	1.3	0.1	0.3
Waste from mains, stoves and boilers (est. 30 per cent of quantity recovered).....	0.1	0.4		0.1
Lost in stack gases.....	2.6	11.2	1.1	3.1
Total.....	22.4	100.0	35.6	100.0

but the percentage is too low to justify reclamation in this way. However, the potash now lost in wet washers and from stove and boiler-house stacks offers a legitimate and inviting field for its recovery. According to our balance sheet, it appears that about two-thirds of the total potash charged is now lost in the wash water and stack gases, or about 15 lb. per ton of pig iron produced.

About two years ago we obtained estimates for cost of recovery of the flue dust from several of our large boiler-house stacks, both by filtering and electrical precipitation methods; but the relatively high cost and the uncertainty in the potash market, deterred an actual installation. Later it was realized that the principal loss of potash was not from the stacks.

At intervals during the course of the last year or more, we have had in operation an experimental Cottrell electric dust precipitator, connected to the raw gas main leaving one of the dust catchers. It is not my purpose in this paper to discuss the operation of the unit, except to state that practically all the dust and fume entering the treater could be precipitated successfully. The color of the dust recovered varied from a light to a dark gray. Several samples were analyzed and showed a potash content of about 10 per cent. The total dust leaving the dust catcher is evidently very much richer in potash than the relatively heavy particles constituting the dust in the dust catchers. However, with the above knowledge at hand, and judging from check calculations on total dust leaving the dust catchers and its theoretical potash content (by difference), it is my opinion that the estimated weight (by difference) of potash lost in the primary washers is somewhat, though not greatly, too high. For our average practice, there should be not less than 12 lb. of total, and probably about 9 lb. of water-soluble potash, now lost in washers and stacks, per ton of pig iron produced.

It may be mentioned that by weak acid treatment part of the insoluble potash content in flue dust may be rendered water-soluble, though this is not likely to be of practical application. Also, the soluble alkali salts can be recovered in tolerably pure form by leaching and evaporation.

It is not my purpose to develop at length the commercial phase of the subject. With the foregoing figures and present potash-fertilizer value as a basis, anyone can readily determine what a very attractive proposition is the recovery of potash from blast-furnace gas at the present time. A word of caution may be appropriate. As previously indicated, the weight of potash

charged per unit of iron produced is above the average at Bethlehem. There are only two or three apparently practical methods for recovery on a large scale of potash from blast-furnace gas, and they are expensive and as yet untried for blast-furnace conditions. The price of potash is certain to fall after the war.

On the other hand, the recovery of potash in connection with the thorough dry cleaning of blast-furnace gas, with certain obvious advantages as against wet cleaning, is an attractive proposition to plants now suffering from burdens rich in alkalies. I venture to predict that in the future dry cleaning will be adopted in many blast-furnace plants, and that many thousands of tons of potash, hitherto wasted, will be reclaimed. Thus will our national resources be strengthened in this important raw material, and the blast furnace will have added another material to its increasing list of by-products.

The subject of alkalies in blast-furnace practice is of a difficult and complicated nature. It will afford much food for thought, both for the philosopher and the practical furnace operator.

Silica Brick and Some New Uses for Them

By Walter Gray, B. S.

Very little has been generally known about refractories and the adaptability of one kind of material over another for a particular class of work. Engineers have been very well satisfied if the refractory material would reasonably withstand the action of the flame and have not experimented, or investigated with a view of securing the most efficient and economical material. To the advent of the by-product coke oven in the United States is due much of the investigations of refractories which have been made. These experiments and others which have been conducted, indicate quite clearly the advantages of silica brick in many metallurgical and industrial operations. The investigations show that the field for the use of silica is not restricted, and that its adoption may in many cases prove a decided economy.

In order to secure a comprehensive idea of silica as well as its advantages and limitations, it is necessary to compare it with the other available commercial refractories. Such a comparison will show clearly the true worth of silica, and will indicate the probability of its success when substituted for another material. The common commercially available refractories are, magnesite, chrome, bauxite, clay brick, and silica brick.

MAGNESIA BRICK

Magnesia brick are manufactured from grain magnesite imported from Austria-Hungary which will analyze approximately 85 per cent MgO. The magnesite is quarried, carefully selected, crushed, and calcined at white heat (approximately 2900 deg. Fahr.) in shaft furnaces or rotary calciners. The calcined magnesite upon arrival in this country is tempered, ground with water, and made into brick without bond, and burned in down draft kilns at a temperature approximating cone No. 29. It is thus seen that the ordinary magnesia brick is the result of two burnings.

Magnesia brick have a very high fusing point, but soften and lose their coherence at high temperatures. This objectionable property restricts their use to operations where they will not be subjected to pressure at high temperatures. Magnesia brick expand rapidly and uniformly with an increase in temperature until the maximum is reached at about 2900 or 3000 deg. Fahr.,

where the softening effect is evident. Chemically magnesia brick are basic.

CHROME BRICK

Chrome brick are manufactured from chrome ore imported from Greece which will contain approximately 40 per cent Cr_2O_3 together with alumina, ferrous oxides, and silica. The ore is ground, formed into brick, and burned in down draft kilns. Chromium oxide is itself not fusible at metallurgical temperatures.

Chrome brick, however, due to the fact that there is but 40 per cent of the oxide present, soften at lower temperatures than magnesia brick and are consequently less strong and less resistant to deformation at high temperatures, and will often if loaded prove unreliable at temperatures above 2800 deg. Fahr. At lower temperatures chrome brick are dense and hard and stand abrasion well, but possess the objectionable feature of spawling with sudden changes of temperature.

Their chief value lies in their chemical neutrality, for chrome brick are neither acid, basic, reducing or oxidizing.

BAUXITE BRICK

Bauxite brick are manufactured from the alumina ore of the same name. Pure bauxite is light gray in color, but as it is generally found associated with impurities, the ore is generally red, yellow, or brown. Geologically it is regarded as decomposed basalt, chemically it is a hydrated alumina containing various quantities of aluminium silicate and hydrated oxides of iron.

In order to reduce shrinkage the bauxite has to be thoroughly calcined before being made up into brick and this materially increases the cost. In calcining, the material contracts little, until after the temperature has risen above 2390 deg. Fahr., when excessive shrinkage takes place, the maximum being reached at 2500 deg. Fahr. Water of combination to the amount of approximately 30 per cent of the weight of the raw ore is driven off.

The calcined material is mixed with from one-third to one-sixth part of plastic fire clay and with the addition of water is thoroughly worked and molded into brick and burned at the highest temperatures obtainable in the kiln.

Bauxite brick exhibit a highly basic tendency, the Al_2O_3 content running up as high as 55 per cent to 85 per cent. Although the fusing point of bauxite brick is very high, they have the objectionable property of cracking on sudden changes of temperature. By burning at the highest temperatures obtainable in the kilns, much of the shrinkage which was always detrimental to settings or linings made up of bauxite brick, has been done away with, and now bauxite brick are beginning to be used extensively.

FIRE CLAY BRICK

We are all more or less familiar with fire clays. Fire clays are the result of decomposition of igneous rocks high in feldspar, which, under the influence of weathering, result in kaolinite. Calcined kaolinite will analyze approximately 46.09 Al_2O_3 and 53.91 SiO_2 , and is representative of perfect fire clay. These kaolin deposits are stratified upon deposition, and are often subject to considerable pressure, which causes the clay to become hard and dense.

Chemically, fire clays are double silicates of alumina and consist of hydrous silicates of alumina, together with impurities in the form of iron, alkaline silicates, and water, either chemically combined, free, or both. Free silica in excess of the amount required to unite with the alumina will unite with the impurities, act as

a flux, and materially lower the fusing point. The alkaline content should be very low, not over 2 per cent, and the iron should be present in very small quantities, as 5 per cent will make the brick worthless. The amount of iron present is a direct indication of the fusibility of the brick.

The fire clays usually occur underneath the coal measures and require underground mining. The deposits consist of two kinds of clays—the hard flinty clays which are the heat resisting element in the brick, and the soft, plastic clays which form the bond. The hard or block clay, as it is called, very often occurs in the same vein with the soft clay, but is usually above the latter of less depth, and often not separated by any clearly defined line of demarkation. This relationship may reverse itself both as to position and quantity, and sometimes the two are even intermingled. The clays when mined are broken by a hammer, carefully selected, and stocked in piles. The proper proportions of crushed lean and plastic clays, together with "grog," the trade name for ground brick, or calcined clay, are ground in the wet pan with sufficient water to give the required consistency and molded into bricks. When worked between the thumb and finger, it gives a decided sticky feel. The shapes are dried bone dry on a hot floor or in a dryer, and are burned in down-draft kilns at a temperature approximately 2500 deg. Fahr.

SILICA BRICK

Before the advent of silica brick, natural siliceous rocks such as sandstones, granites, gneiss, and quartz porphyry had been quarried, carefully dressed, and used as refractory linings. Even at the present time mica schist is still extensively quarried for use in lime kilns. The use of such rocks, however, was not altogether satisfactory; due to physical defects and exfoliation, they suffer severely from the action of the heat. The introduction of silica brick followed quite naturally, for a light uniform shape easily handled and easily laid had everything in its favor, and speedily superseded the natural rock.

RAW MATERIAL

Silica brick are manufactured from a sandstone or quartzite which is of sedimentary origin. On account of certain physical features which are very necessary for the manufacture of a well-bonded brick, brick manufacturers are restricted in the selection of their raw material to certain parts of Pennsylvania and Wisconsin and Alabama. For the successful manufacture of brick the siliceous material must be in the form of a rock and not a sand or gravel. The rock should be hard, dense, metamorphic, and semi-crystalline in structure, not granular, with little indications of lime, talc or clay, and with little discoloration from iron. When ground, the grains should appear splintery, sharp, heterogeneous as to form and size, and slightly translucent. It is the physical roughness of the material that gives the brick its strength. The more homogeneously knit together the grains are which compose a brick the better service it will give. Pure quartz, rounded pebbles, or grains of sand, or too coarse crystals prove undesirable as they will not bond tightly. In gneiss rock, such as silica brick are made from, the cementing element is as hard as the quartz grains, and upon grinding the particles do not become rounded, but interlock in the brick and bond well.

A suitable quartzite should analyze approximately 97.5 SiO_2 , 1 per cent to $1\frac{1}{2}$ per cent Al_2O_3 , 0.75 per cent other impurities, smelt at cone 35 to 36, expand, and swell without perceptible cracking. The total fluxes should not exceed 3 per cent. Alumina, if in the form of kaolin

or a silicate, should probably be not higher than $1\frac{1}{2}$ to 2 per cent.

QUARTZITE

In America we have to distinguish between two kinds of silica refractories: First, brick high in silica, known as ganister or lime-bond silica brick, in which the bonding agent is lime; second, brick lower in silica, known as quartzite, in which clay is the bond used. Although not so strong physically as the clay brick, quartzite possesses the advantage of being easily worked and expands with increases of temperature, but in a much less degree than silica. Quartzite brick will analyze approximately 70 to 75 per cent SiO_2 and 21 to 26 per cent Al_2O_3 . They are manufactured by adding approximately one part of fine ground clay to two parts of crushed quartz, mixing with water and forming into brick.

MANUFACTURE OF SILICA BRICK

The two most important deposits of ganister, the trade name for silica rock, best suited for the manufacture of silica brick are found in the Mount Union district of Pennsylvania and the Baraboo region of Wisconsin. The Mount Union rock is fine grained, grayish white in color with tinges of yellow, and showing slight discoloration from iron. The Wisconsin quartzite is much darker in color due to a larger content of iron, and seems much more crystalline in structure. It is denser and harder to work than the Mount Union rock, and has evidently been subjected to a greater pressure, with perhaps some heat. The ganister rock found in the South near Birmingham, Ala., resembles very closely the Mount Union rock, both in its physical and chemical properties. These various rocks will analyze approximately as follows:

SiO_2	0.98%	Lime	0.20%
Al_2O_3	0.60%	MgO	0.10%
Fe_2O_3	0.70%	Alkalies	0.40%

Silica rock is almost never mined at depth, but as in the case of the Mount Union district is collected in the form of boulders and fragmentary pieces which have been torn from the parent ledges and strewn over the surrounding territory, sometimes to a depth of 4 ft. or even considerably more, or else it is quarried from the shelves or ledges. When too large these boulders are shattered by blasting and the fragmentary pieces are carefully examined for impurities, and all ferruginous, calcareous or argillaceous rock are rejected. The rock is then transported to large open yards. When required for the manufacture of brick it is crushed to a suitable size in gyratory or jaw crushers. The broken material is then conveyed in buggies to the wet pan, and ground beneath the rollers by a few revolutions of the pan before the milk of lime is added. Only pure soft white lime manufactured from limestones high in calcium carbonate is used. The lime is mixed with the proper quantity of water stored in tubs and fed in proper proportions into the wet pan, usually 2 per cent by weight, and the grinding resumed. Great care is taken to see that the right proportion of lime is added so that it will produce a well-bonded, hard-ringing, clinkered brick. In analysis the lime will often show up as 1.75 per cent, due to losses, but great care is taken that never more than 2 per cent is added, as a material reduction in refractoriness would result.

The material, when ground sufficiently fine, is but slightly damp and, unlike the clays, possesses practically no plasticity, and when worked between the thumb and fingers resembles in feel and appearance moist fine sand. To the trained sense of touch there is a considerable difference in the feel of the material from the different pans, due altogether to the manner in which water has been added and the material worked. The moulder

who receives the ground mixture pounds and works it into the mould with his fingers and trowels it smooth. The moulds are of steel, and make several brick, depending on their size, at the one operation. A steel plate which forms the shelf in a rack car also forms the bottom of the mould, and when the mould is withdrawn it carries the shapes. The rack cars are run to the dryer, or in the case of larger shapes to the hot floor. The drying takes approximately ten to twenty hours, depending, of course, on the size of the shape. Large shapes are laid on the hot floors and turned from time to time. Difficult shapes are less often made in silica than in clay, due in a large measure to the great care required in drying them to prevent cracking, and due also to the lack of plasticity of the material.

The brick are stacked with great care in the kiln, the ordinary standard shapes being placed on edge and bonded at intervals with burned bats. Openings somewhat on the order of checkerwork are left through which the flame can pass and escape through the riddle flues in the floor. The brick are protected from fire flashing by a checkerwork of burned bats built around the firebox. Great care is observed in the setting of the shapes so that they will not only be subjected to the required temperature, but will also sustain the load and not allow a slip to occur, which might prove detrimental to the entire charge. Difficult shapes because of their size or fragility are generally carefully placed high in the kiln where they will have to carry but little weight. The kilns are usually round kilns of the down-draft system, fired with coal, and will hold, depending on their size, anywhere from 30,000 to 100,000 brick at a single firing.

The operation of burning may be divided into three periods. During the first period the brick are thoroughly dried and the moisture removed. This is necessarily a very slow process and cannot well be hastened. Three days are required to drive off the moisture, the temperature gradually being raised to approximately 300 deg. Fahr. Considerable air is admitted throughout this stage of the drying. During the intermediate period, which will last for approximately four days, the temperature is gradually increased and the draft steadily diminished. The carbon dioxide passes off from the lime and the oxidation of any ferrous iron to the ferric condition occurs.

During the burning proper, which forms the third period, the clinker is formed. This clinker is the slag produced by the combination of the lime with the silica. This is a lime silicate, but its character is made more complex by the addition of the Al_2O_3 and the Fe_2O_3 , which occur in the brick, and unite in forming the slag. This slag glazes over and binds the particles of quartz, and in shrinking makes the brick porous and produces the property of clinkering or producing a ringing sound when struck. During the burning period there is but very little excess air allowed in the kiln, and the temperature is forced up to 2800 deg. or 3000 deg. Fahr. and the brick kept at a soaking heat for three to four days. The final temperature should always be higher than the temperature the brick are to encounter in actual practice. When the brick in the kiln have been kept at the required temperature as indicated by Seger cones for a sufficient time, the dampers are closed, the fires are allowed to die out and the kiln allowed to cool off. Great care is observed to prevent drafts of cold air from striking the heated brick. The kiln necessarily cools very slowly, and ordinarily it is two days after the fires have been extinguished before the kiln can be opened. Four or five days more elapse before the brick are sufficiently cool to handle and sort and wheel to the storage sheds for shipment.

PROPERTIES OF SILICA BRICK

Very little real scientific investigation has been made with a view of determining the physical properties of firebrick. Many manufacturers have used only a thumb-and-rule method in making their brick, and have secured satisfactory results more by good luck than good management. Indeed, so content have they been with this haphazard system that they have looked upon all experiments in the research laboratory as interesting but not essential, and far too expensive.

Keen competition and the increasing use of refractory materials in many new industrial operations have caused the brick manufacturer in recent years to study his product with a view of determining the adaptability of one refractory over another for a particular class of work. Indeed, the manufacturers are just beginning to realize that the question of refractoriness, vital as it is, is not always the all-important one. Expansion, abrasion, conductivity, and especially the ability of the material to withstand pressure at operating temperatures, must be considered if a highly efficient and economical material is to be produced. It is only within the last few years, with the widespread adoption of the by-product coke oven, that the very important questions of expansion and conductivity have been seriously considered.

La Société d'Encouragement pour l'Industrie Nationale of France, believing that a more comprehensive knowledge of the properties of refractories would be of inestimable value, granted S. Wologdine a research scholarship and placed laboratories at his disposal. With this and one or two other exceptions such experiments as have been made have as a rule been conducted by the brick manufacturers themselves.

CHEMICAL PROPERTIES

In general, the chemical analysis gives a very good indication of the quality and refractoriness of a brick. The actual fusing point, however, is dependent also in a large measure on the size of the grains, the homogeneity of the mass, the burn, and the mineral elements which comprise the brick. However, in silica, a chemical analysis is of very great importance, as the refractoriness depends directly upon the amount of lime, alkalies and iron present. The silica content should be about 96 per cent, the lime $1\frac{3}{4}$ per cent to 2 per cent, and the alumina and iron about $1\frac{1}{2}$ to 2 per cent. As a matter of fact, silica brick will analyze approximately as follows:

SiO ₂	96.0%	Lime	1.75%
Al ₂ O ₃	0.90%	MgO	0.14%
Fe ₂ O ₃	0.70%	Alkalies	0.39%

Possibly it would be well to explain here the seemingly inconsistent statement that a high-alumina, low-silica firebrick is more refractory than a brick comparatively high in silica, and that a lime-bond silica brick is the equal or superior of a high-alumina fire clay brick. This is explained by the fact that the alumina and silica, which unite to form the alumina silicates of clay brick, are capable of combining in almost any proportion from 1 molecule of alumina to 2 molecules of silica, or from 1 molecule of alumina to 17 molecules of silica (10 alumina to 90 silica by weight). Seger made several tests using cones composed of various proportions of chemically pure precipitated alumina and silica, increasing the silica in multiples of one part of alumina. This relative increase of silica added to one part of alumina was used as ordinates, and the various Seger cones, indicating temperature, were used as abscissæ to plot a curve which would graphically show the fusing point for any combination.

The maximum refractoriness, as indicated by the

highest fusing temperature, is 1 molecule of alumina and 2 molecules of silica which fused at approximately cone No. 37 (3393 deg. Fahr.). The curve drops as we continue adding silica until at about 17 parts silica to 1 of alumina the fusing point is indicated at approximately 3160 deg. Fahr. by cone No. 29. This is the eutectic point of the curve, for as silica is further in-

FIG. 1.—CURVE SHOWING EFFECT OF ADDITION OF SILICA TO ALUMINA

creased the refractoriness rises until with the proportion of 30 silica and 1 alumina a fusing point of 3300 deg. Fahr. is obtained.

These results are due to the fact that an excess of silica in a clay brick is present in the form of quartz, and acts as an impurity and tends as all impurities do to depress the refractoriness. The curve shows us that we may expect maximum refractoriness in a high alumina brick, such as bauxite, and also in a high silica brick, such as lime-bond silica, and lower refractoriness in a combination of alumina and silica, as in the case of quartzite, which has closely the proportions of alumina and silica referred to as cone No. 17.

Silica, the opposite of magnesia, is acid, and is used in metallurgical furnaces operating with acid slags to form a stable lining. It is very soluble in strong alkaline solutions, easily attacked by metal oxides and flue dust.

PHYSICAL PROPERTIES

Refractories naturally group themselves into acid, basic and neutral materials, and it is, of course, obvious that where a slag is to be encountered its chemical nature determines to a large extent the refractory material to be used. In other operations, where such limiting conditions do not exist, or at least only in a slight measure, an investigation of the physical properties of the refractories material will assist in determining the best brick to use.

Silica brick are straw colored, smooth of surface, with sharp, well-moulded corners, and present upon breaking a coarse crystalline fracture, discolored occasionally by reddish-brown spots showing the presence of iron oxide. These spots may be due either to iron naturally contained in the rock or may result from the oxidation of small pieces of metallic iron which has been worn from the pan rolls or crusher jaws and been incorporated in the brick.

A 9-in. straight weighs almost exactly 6 lb. and has a specific gravity of 2.4, is quite porous, brittle, and not easily worked.

Silica brick are the ideal brick to use where a high and constant temperature is to be encountered, and where the chemical action of the slag is not detrimental. Silica, however, possesses the objectionable feature of sprawling or disintegrating if subjected to blasts of cold air or irregular cooling when hot. Great care should always be exercised to bring silica brick up to

their working temperature slowly and evenly, for not only does too rapid heating cause excessive spawling, but materially lowers the refractoriness of the brick.

After the original heating, the brick become annealed somewhat, and such great care is not necessary. Indeed, the abuse that silica brick will stand after proper treatment in the original firing is wonderful. Silica brick, like chrome and magnesia, expand when heated, and for this reason are of great value when used in domes or arches or gas-tight chambers, as in expanding they tend to keep everything tight and in alignment. Fire clay brick, on the other hand, contrary to popular belief, expand a slight amount upon heating, but shrink very considerably when cooled, and the fire clay with which they are laid may shrink so much that it opens up the joints and allows the brickwork to settle badly. Silica, even if badly cracked and checked, expands sufficiently to keep the structure tight and in position. Furthermore, silica brick retain their shape and refractoriness practically to the point of fusion, and are capable of supporting loads of 75 lb. per square inch or more at temperatures well above 2700 deg. Fahr. or 2800 deg. Fahr. Magnesia and chrome brick, it will be recalled, soften, and are subject to considerable deformation at high temperatures, while a fire clay brick, if submitted to such a test, would deteriorate and squeeze out of shape.

With standard brick there is no distinction made in regard to grind or burn, as is the case with clay. In shape work the grind is usually finer to insure a more perfect filling of the mould and produce a better appearing shape. The fineness of the grind making a more intimate mixture of the lime and silica resulting in a better slagging effect will increase the strength of the brick. Silica brick are considerable more refractory than clay brick, although not as refractory as chrome or magnesia. They will not melt at temperatures under approximately 3400 deg. Fahr., as compared with 3900 deg. Fahr. for magnesia and 4000 deg. Fahr. for chrome. In silica brick the softening and fusing points are almost identical.

Expansion.—Standard 9-in. silica brick will expand as much as $\frac{1}{8}$ to $\frac{1}{4}$ in. in length and $\frac{1}{8}$ to $\frac{3}{16}$ other dimensions in burning in the kiln, from the green shape to the commercial brick. This increase in volume is accounted for by, first, an increase in the size and number of the pores; second, an expansion of the mineral itself, and, third, the change of the quartz into tridymite. At approximately 1050 deg. Fahr. quartz goes into another crystalline form, then into betaquartz, and at 1800 deg. Fahr. in to tridymite, remaining in this form between 1800 deg. and 2900 deg. Fahr. According to one authority this transformation is accompanied, in the case of a pure quartz, by an increase in volume of approximately 10 per cent. In an ordinary brick, it is believed by many that only one-third to one-half of the whole amount of quartz present has been changed into tridymite, and that the remainder is changed more slowly in the furnace. However this may be, it is always the brick manufacturer's aim to burn all the expansion out of the brick in the kiln, but such a state of equilibrium is never reached. A good silica brick should show a considerable expansion on first burning and a relatively small expansion thereafter.

Porosity.—The test for porosity is made by heating the brick to expel all moisture and weighing it, then immersing it in boiling water for several hours, allowing all included air to escape. The difference in weight before and after immersion is a direct indication of the porosity. Silica brick in test will show a porosity of 10 per cent by weight and 20 per cent by volume after immersion for several hours in boiling water.

They are generally more porous than quartzite or clay brick.

Density.—The density varies with high temperatures, diminishing as the temperature is increased proportionally to the contraction in the pore space. In the case of silica Wologdine found the density decreased regularly until at 2500 deg. or 2600 deg. Fahr. it was approximately 2.57. This decrease in density is accompanied by only a slight change in porosity. Pure magnesia, on the other hand, shows a marked change in porosity. This change decreases, however, instead of increases, as in the case of silica. The higher the brick is in impurities the lower is the temperature at which the drop in specific gravity becomes manifest. It is evident that a curve correlating burning temperature and density will give a very good expression of the refractory qualities of the brick.

Permeability.—As a general proposition the heat conductivity of fire clay and silica refractories is that of the air enclosed in the pores, and not that of the material itself. From this it is evident that conductivity and permeability increase with the porosity and vice versa. It is also evident that the size of the grain and other physical conditions will influence the permeability, the most noticeable of these being the burning temperature. Wologdine discovered that silica brick burned at 1050 deg. C. and had a permeability of 3.3 liters per hour, but at 1300 deg. C. their permeability had increased to 192 liters, and at 1400 deg. C. to 241 liters per hour. This shows that the permeability may vary in a very marked degree, while the other physical properties may change but slightly with the increase of temperature. This is accounted for by the great change in pores and capillary openings due to the transformation of the silica during vitrification.

Conductivity.—It is very much to be regretted that the information which is available on this property of refractories is limited to low temperatures. As heat conductivity increases quite rapidly with an increase in temperature, the importance of information on conductivity at operating temperatures is obvious. Experimenters have been limited by the great difficulties of measuring heat at such high temperatures and the physical limitations of the apparatus used. The experiments which have been made have employed temperatures usually not exceeding 400 deg. or 500 deg. Fahr., and only in rare cases have higher temperatures approaching the working condition of the refractory been used. Wologdine reached temperatures of 1000 deg. to 1200 deg. C. in the experiments that he made.

The results of a rather interesting experiment showed that to melt paraffine by heat conducted through $4\frac{1}{2}$ in. of brickwork 48 minutes were required for clay brick, 45 minutes for quartzite, 39 minutes for silica, $32\frac{1}{2}$ minutes for chrome and $17\frac{3}{4}$ minutes for magnesia brick. Another test, using, however, rather low temperatures, showed magnesia to possess the greatest conductivity, with chrome second and silica third, and the clay brick following in sequence in the order of their densities, the lighter densities showing the higher conductivity.

From this, as stated above, we infer that conductivity is a direct function of the density. Density, it will be recalled, is dependent upon the fineness of the grains and the temperatures of burning. It has been shown by experiment that the conductivity of firebrick increases with the temperature of burning; that is, the higher the burning temperature the greater the conductivity. Wologdine found a unique exception to this rule to be chromite, the heat conductivity of this material being independent of temperature. Silica has approximately 20 per cent greater conductivity than clay

brick, whereas the conductivity of magnesia is double that of clay. The increase of conductivity will vary considerably. Wologdine found that bauxite brick increased one and a half times in conductivity when burned at 1300 deg. C., as against 1050 deg. C., whereas in the same range of 250 deg. C. magnesia showed an increase of but 5 per cent.

Load Test.—It is generally conceded that the load test is the fairest criterion of refractories. Its chief advantage lies in the fact that it will give a very adequate idea of the behavior of a refractory under operating conditions. Other tests do not always include such considerations. A brick which may show high compressive strength at atmospheric temperatures may fail utterly or possess only a small portion of this strength at high temperatures. A compressive test on cold brick is desirable, but aside from the fact that a weak brick is always a handicap, such a test gives practically no information regarding its resistance to deformation at high temperatures. The load should be somewhat greater than actual furnace loads, as in tests the time element, which is a very vital factor in actual operation, cannot receive attention.

The brick are either loaded singly or built into columns. In either case they are carefully measured in order to calculate the shrinkage and deformation. The results of many tests show that silica is the only brick which will support its own weight, or a reasonable load, without deformation at high temperatures. Quartzite and clay brick begin to show settling at temperatures approximately 400 deg. to 500 deg. Fahr. lower than the temperature at which they were burned. Quartzite brick settle rapidly out of shape from their own weight at temperatures approximating 2700 deg. Fahr. It is evident from this that the range between the softening and fusing points decreases, as the silica contents of a clay brick increase. Silica brick usually show in such tests, especially if built in columns, an increase in height, due to expansion, whereas the clay brick column will show a shrinkage of almost 5 per cent of its original height and the bricks will be fused together. As an illustration, the results of a typical test might be mentioned. Columns were built of silica, quartzite and clay brick, loaded and heated to high temperatures. The silica column supported a weight of 75 lb. per square inch, was subjected to a temperature of 3200 deg. Fahr., and was in good condition at the completion of the test. A similar column made up of clay brick heated to 3100 deg. Fahr. and supporting a load of only 27 lb. per square inch suffered bad deformation. The quartzite column under similar conditions did not prove as reliable as the clay brick.

By plotting a series of failing loads against the chemical impurities in the brick a very good idea can be obtained of the manner in which these impurities affect the refractoriness and resistance to deformation, for it is due to their presence resulting in low fusing points that the test pieces fail.

Special Uses of Silica Brick

In calling attention to special uses of silica brick, no claim is made that they will prove a panacea for all the troubles and shortcomings experienced with refractories used in similar metallurgical and industrial practice. Whether or not silica would answer equally well in other operations and under other conditions than the cases to be described is something which only careful study and experiment can determine. Much of the information given was secured from the Harbison Walker Refractories Company. The cases cited are from actual practice and the results described are the observations of operators and men who have been in actual touch

with the plants and conditions under which these silica brick have been used.

In presenting these special uses of silica brick, the only claim that is made is that satisfactory results have been secured from them in the particular uses to which they were put, and that they have in many cases proven an economical substitute. These results, because of their uncommon interest, justify their incorporation in this paper.

OPEN-HEARTH CHECKERS

It is interesting to note that the use of silica in open-hearth furnace construction is continually increasing. Formerly the checkerwork was composed entirely of clay brick, and often of not any too good quality. Some steel plants have found it advantageous to use a few courses of silica brick upon the top courses of the checkers. Even the best clay brick when used here fuse and become vitrified. The carbon and particles of slag and limestone carried over by the flue gases permeate and coat them, destroying in a large measure their ability to absorb and give off heat readily.

Silica brick, it is claimed, are less readily choked up, as the carbon coating does not seem to penetrate them and adhere as in the case of clay brick. As they do not fuse or vitrify, being sufficiently refractory to withstand the heat, they not only give many times the life of clay brick, but can be used over several times. Indeed, so favorably have they proven for this class of work that many open-hearth plants are making all their checkerwork of silica, with the exception of the last few courses, which would be subject to spawling due to sudden and wide variations in temperature. Not only is the load on the girder arches considerably less, because of the lighter weight of silica brick, but it is claimed that due to its higher porosity and conductivity the use of silica exerts a marked influence on the quick working of the furnace.

BOILER FURNACES

Silica brick have rarely been used in boiler settings and coking arches. Their objectionable property of spawling when struck by a draft of cold air would make them almost prohibitive in such a practice.

They have, however, been tried, and in one or two cases where they were protected from drafts of cold air, and where the heating was gradual and the boilers were not forced, they have given satisfaction and have outlived clay brick, and been quite free from clinkers.

In this connection, it is interesting to note that bauxite brick are being tried in boiler furnaces with gratifying results. They are particularly free from clinkers, such as form on clay brick. Like silica, however, they have a tendency to sprawl on sudden changes of temperature.

BEEHIVE COKE OVENS

The use of lime-bond silica brick for the crowns of coke ovens is not new, but possesses some very interesting features. Here we see silica used under conditions which seem most detrimental to its success.

In the original firing some care may be observed in heating the ovens up gradually, but the very nature of coke manufacture makes almost any such attention subsequently impossible. Drawing the oven when at its highest temperature, leaving it to cool very quickly with drafts of cold air impinging on the brickwork, exerts a very detrimental influence. An examination of any coke oven crown will show that the brick have spawled and cracked very badly due to the severe treatment received. However, the expansion of the silica and the taper of the brick retains the pieces in the dome.

When once the crown has become cracked or parted throughout, so that the tendency to spawl is reduced to a minimum, and the brick have become annealed, the crown may be good for a great many years. It seems strange that silica brick used under most trying conditions should be the only satisfactory material for this purpose. Their universal adoption is sufficient proof of their value, as against clay brick, the best of which does not seem able to withstand the high heats for any length of time, but slowly melts and runs, and finally falls from the setting.

LIME KILNS

The use of silica brick in the construction of lime kilns is a new departure. On account of its refractoriness and proximity, mica schist has been used extensively for the eyes and piers of lime kilns; indeed, many lime burners say it cannot be excelled. Silica brick, on account of the ease with which they can be moulded into any shape or form and handled, are being tried out by quite a few large lime companies as a substitute for mica schist. The use of silica as a lining material for burning lime may seem paradoxical and contrary to the axioms of chemistry, but when the fact that lime and silica do not combine to form a silicate at the temperatures at which the lime is burned is considered, its use does not seem so unreasonable.

Silica brick have been used generally in the barrel of the kilns, and extend anywhere from a few courses above the eyes to as much as 15 ft. above the arches, the remainder of the stack being clay brick. It is in the barrel of the kiln that the severest action takes place. The hot limestone, when it has worked down this low in the kiln, is semi-plastic and soft and hangs in the shaft concentrating the heat and burning out the lining. The eyes are located at this portion of the kiln and are the weakest point in its construction. They are subjected not only to the intense heat of the fuel and the hot stone, but also to the detrimental effects of drafts of cold air striking the heated brickwork every time the firebox doors are opened.

The kilns of eight large lime companies widely separate, who were probably the first to use silica with any degree of thoroughness, have been selected as representing the most reliable sources of information. Four of these companies manufacture high calcium lime and the other four make a high magnesia lime. Of the high calcium kilns, one is rotary and gas fired, the remainder are of the vertical shaft type and coal fired.

In the rotary kiln silica is used in the hot zone to replace high-grade fire clay and chrome brick, resulting in an increased average life of twelve months, as against a previously maximum of three months. The vertical kilns are lined in the barrel, and in the arches and piers with silica brick.

With the exception of one kiln, in which the heats were brought up in two hours and no care had been exercised in first firing, the results from using silica brick are most gratifying. One company that is securing approximately twice the life from silica that they had secured from high-grade clay observed great care in firing their kilns. The heats were brought up very gradually for the first twelve hours, and only attained their full intensity after thirty-six hours. After this first firing, however, the silica linings are treated with no more care than ordinary clay brick. In twelve months' service the piers in the kiln had been reduced in cross-section only 25 per cent, due to direct impact of the flame and severe service.

Of the four kilns-producing high magnesia lime, but one of them (which is rectangular in shape) is producer-gas fired. It is lined with silica brick in the eyes and

barrel and promises to outlast any previous clay lining. All the other kilns are coal fired. In one kiln, in which silica brick has replaced the arches and jambs, formerly made of mica schist, it gives considerable better life at approximately half the cost, and has proven so satisfactory that this company intends using it in five other kilns.

The largest of these companies, manufacturing high magnesia lime, has one kiln of the Eldred system which was first fired in April, 1911. It is lined in the eyes and barrel with silica brick and has now been in operation for two years and is in such condition that with some minor repairs to the arches, due to sprawling, it may last for a much longer period. The decision of this company to line four more kilns with silica brick is conclusive proof of satisfactory results.

An interesting feature of the use of silica brick at this plant was the failure of the lime to stick or hang, it is claimed, so that considerable of it passed through under-burned, causing a decrease in capacity of approximately 8 per cent a year. This is undoubtedly due to the exceptional refractoriness of silica brick and its failure to in any way flux with the calcining lime. On clay brick the lime will often clinker, forming "monkeys," which in breaking loose tear the brick out with them. By corbelling the brickwork so as to give a purchase for the descending lime this trouble was obliterated, and there has been no recurrence of it either here or at any other plant.

These results indicate that the use of silica brick may mean a decided increase in the life of the kiln lining and result in a considerable economy in operation. Where failures have occurred they can almost always be traced back to injudicious management and poor handling. Where the best results are to be obtained great care must be exercised in the initial heating. The temperature should be brought up gradually and slowly, especially for the first 600 or 800 deg., as it is in the first heating that there is so much danger of spawling. After having been well tempered, silica brick will stand an extraordinary amount of abuse.

CUPOLAS

The use of silica brick in cupolas is as interesting as it is unique and uncommon. There are but two or three such cases which have come to the writer's notice.

One company which manufactures steel castings has been using silica brick in its cupolas and for lining its ladles for some four years, and with marked success. This company uses about four or five courses of silica brick in the melting zone of its cupola, and backs them up with standard clay firebrick. The brick are laid tight in silica cement and no extraordinary allowances are made for expansion. In lining its Tronepas converters, however, a space of an inch and a half is allowed against the shell for packing and expansion. No serious trouble has been experienced due to spawling, as the heats are increased slowly. The cupolas are, however, shut down cold each day after a run of ten hours, and in quenching the charge no great pains are taken to prevent the steam from striking the heated brickwork. No accurate records have been kept by this company regarding the life of silica brick, but it is roughly estimated as three to one in favor of silica against high-grade clay, and it is believed this estimate is very conservative.

The ladles used by this company are lined entirely with silica brick, with the exception of the top courses, which are clay brick, as silica would spawl badly at this point, where the hot metal and the atmosphere both react on the brickwork. The linings show a tendency to spawl if heated too suddenly on the first pour. After

a few heats, however, the brick become slightly glazed over, due to the action of the hot metal and the slag, and receive such a hard durable surface that no further trouble is experienced, no matter how quickly the ladles are heated. Each ladle is used for approximately fifteen heats of 5000 lb. each. The life of silica in these ladles is approximately seven times as great as the life of the clay brick formerly used.

Another company, which on a test secured four weeks' longer life with silica than with any clay brick previously used, have relined their cupola stacks for quite a way up with silica brick. Although the brick have been in but for a short time, they are getting twice the life secured from any clay brick formerly used.

BY-PRODUCT COKE OVENS AND GAS RETORTS

Silica has almost entirely replaced quartzite and clay bricks in by-product coke ovens and gas-retort settings. The rapid development of the by-product oven and the thorough investigations and experiments carried on by expert engineers are responsible in a very large measure for the adoption of silica brick. Indeed, the progress which has been made and the results which have been secured are attributed directly by the oven builders to the use of silica.

The physical limitations of clay or quartzite brick do not make their use desirable. In order to secure a high-grade coke, it is important that the chambers should be heated uniformly, and that the coking temperature be high and the time of coking short. It has been found that to decrease the duration of coking has resulted in a much better grade of coke. Also gas of high candle-power is produced in a retort if the charge of coal is large, leaving a minimum amount of retort surface to act upon the gas as it is generated, and if the temperature of the retort is high, resulting in rapid gasification. The hydrocarbons are thus made permanent gases and the tendency to dissociation into other forms of hydrocarbons of lower candle-power minimized. The heavier charges and shorter periods of carbonization have required heats far in excess of that which the old clay retort could stand. Such temperatures as are now employed approach the softening point of clay, and would cause excessive shrinkage and deformation in the old style clay retorts.

The ability of silica brick to stand up and retain their shape at the temperatures encountered in modern gas retorts and by-product coke ovens has made possible the high state of development to which they have been brought. Silica coke oven or retort shapes keep their alignment and neither sag nor bulge. They give considerably longer life than clay shapes and do not have to be renewed so often. As silica has approximately 20 per cent greater conductivity than clay the temperature inside the retort or oven is higher and the time for the distillation of the volatile matter considerably less. The higher the heats, the greater output and the shorter coking time results in a fewer number of benches or ovens for the same plant capacity as compared to clay linings. The expansion of silica brick is a very valuable feature, for if it were not for this property it is doubtful, with sectional retorts and long coking chambers, whether small shapes could be used at all. It is certain, that the expansion tends to keep everything gas tight. In laying the shapes, this expansion is usually taken care of by paper joints. Silica retorts and ovens are not only particularly free from clinkers, but the carbon deposits do not seem to penetrate them as is the case with clay. This results not only in increased heat transference, but saves the brick from severe scarring action in cleaning, and as the necessity for cleaning is

reduced, the retorts or ovens will be out of commission less frequently.

Actual comparisons between the life of clay and silica in by-product coke ovens are not at hand, but it is a well known fact that silica will give many times the life of clay and in addition prove a great economy in operation. In the case of gas retorts, however, we have a very good comparison. Mr. Samson, in a paper presented before the fourth annual meeting of the American Gas Engineers' Society, described the advantages secured from the installation of silica retorts at the plant of the Worcester Gas Works. The test was made with the same kind of coal which had previously been used in the clay retorts. In the old clay retorts, which were 16 in. x 26 in. x 10 ft., 1 lb. of Westmoreland coal when coked gave 4.95 cu. ft. of 14 cp. gas—practically 70 candle feet. The new silica retorts, which are 26 in. x 26 in. x 17 ft., produced 5.95 cu. ft. of 17 cp.—practically 101 candle feet, from a pound of the same coal. Figures such as these need no further comment; they are themselves conclusive proof of the superiority of silica brick for gas retorts.

CONCLUSION

The cases which have been cited involving special or new uses for silica brick are quite representative and cover a wide range of industries using refractory materials. They show quite clearly that the uses of silica brick are by no means restricted. Indeed, it would seem that the advantages and properties of silica are just beginning to be appreciated and that it is only a question of time until silica will replace clay brick in many industries in which it has long been used.

Harbison-Walker Refractories Co.,
Pittsburgh, Pa.

Movement for Increased Adoption of Metric System Gaining Headway

During the sixty-ninth meeting of the American Association for the Advancement of Science in New York during Christmas week, 1916, a conference was held, designated the "metric conference," at which were present representatives of national business organizations, the United States Department of Commerce and men prominent in engineering and educational work. The object of this conference was to discuss the Pan-American use of the metric system. Its outcome was the formation of a permanent organization to be known as the American Metric Association, to further the adoption of the international meter, gram and liter, which have been legalized in the United States since 1866.

The officers of the Association are as follows: President, George F. Kunz, 405 Fifth Avenue, New York; first vice-president, William Jay Schieffelin, 170 William Street, New York; second vice-president, E. P. Albrecht, The Bourse, Philadelphia, Pa., third vice-president, O. E. Stanley, Portland, Ore.; treasurer, Arthur P. Williams, 56 Hudson Street, New York; secretary, Howard Richards, Jr., 156 Fifth Avenue, New York. The executive committee consists of H. V. Army, 115 W. Sixty-eighth Street, New York; Fred R. Drake, Easton, Pa.; A. E. Kennelly, Massachusetts Institute of Technology, Cambridge, Mass.; S. W. Stratton, Bureau of Standards, Washington, D. C., and W. P. Wilson, Philadelphia Commercial Museum, Philadelphia, Pa.

The association now maintains an office at 156 Fifth Avenue, New York, and is especially desirous of receiving catalogs of manufacturers who use the metric system for domestic or export purposes.

The Processes of the Organic Chemical Industry Used in the Manufacture of Intermediate Products

III. Sulfonations and Caustic Fusions

By A. H. Ney and D. J. Van Marle

Sulfonations are the most common of all operations in the organic chemical industry and consist of the action of sulfuric acid on organic compounds, by which hydrogen is replaced by the sulfonic acid group, the products formed being called sulfonic acids.

The result of a sulfonation depends not only on the nature of the product sulfonated, but also on the amount and strength of the acid, the temperature during the sulfonation, and sometimes the time during which the mixture is heated.

The strength of acid used for sulfonation depends on the nature of the product to be sulfonated as there are products, such as benzol, phenol and naphthalene which are sulfonated very easily and therefore can be treated with ordinary concentrated sulfuric acid, and others, such as nitrobenzol, which only can be sulfonated with difficulty, for the sulfonation of which fuming sulfuric acid must be used. During the sulfonation water is formed, which dilutes the sulfuric acid in the mixture, and makes it necessary to use such an excess of acid that its concentration will not fall below the point, where it would become so dilute that it would no longer act on the material to be sulfonated.

The excess of acid required also depends on the temperature during the sulfonation, for, generally, the same results can be obtained with a larger amount of acid or with a stronger acid at a lower temperature as with a smaller amount of acid or a weaker one at a higher temperature. At the same time it must be taken into account that the temperature also has an influence on the position in which the sulfonic acid group enters the molecule and that a higher temperature sometimes causes more than one sulfonic acid group to enter, so that in every case it must be determined with what strength and amount of acid and at what temperature the best results can be obtained most economically. The heat developed is not so great as in nitrations and is mostly caused by the mixing of the acid and the water formed during the reaction. The temperature, at which sulfonations are carried out, is therefore, mostly higher than in nitrations, and cooling generally unnecessary.

In many instances, where different sulfonic acids are formed at different temperatures, the time also has a decided influence on the result of the sulfonation. Phenol, for example, is converted into a mixture of the ortho- and para-sulfonic acids at a low temperature, while at 100 deg. almost exclusively the para-sulfonic acid is formed, and it has been proven that the ortho-sulfonic acid at elevated temperature is transformed into the para-sulfonic acid. This is not an immediate conversion, but is due to the dilution of the acid, this more dilute acid having a reverse action, and splitting off the sulfonic acid group in ortho-position, which then enters the molecule again in the para-position. This phenomenon is especially of frequent occurrence in sulfonations in the naphthalene-series, the result of the sulfonation being an equilibrium between two or more sulfonic acids, the proportion of the different acids depending on the time of heating. Much better results can be obtained here, if the material is not added to the acid, but is fused and heated to the temperature at which the sulfonation has to be carried out, and the acid run in at constant temperature, whereby the equilibrium is reached in a much shorter time.

As to the position in which the sulfonic acid group

enters the molecule, the following rules can be laid down. In the benzene-series the same rule holds true as for nitrations, a sulfonic acid group entering in meta-position to another sulfonic acid group, a nitro-, carboxyl- or carbonyl-group already present. The sulfonic acid in these cases enters with some difficulty and a strong acid has to be used as well as a higher temperature.

If the product to be sulfonated contains chlorine-, alkyl-, hydroxyl- or amido groups, the sulfonic acid group enters into ortho and para position, their proportion depending on the conditions during the sulfonation, especially the temperature and the kind of acid used, the para-compound mostly being formed in much larger quantities than the ortho-compound.

The hydroxyl compounds are sulfonated most easily, resorcline for instance, being immediately converted into a disulfonic acid, the chlorine-compounds not so easily on account of the acid nature of the chlorine group.

The amido-compounds are in an exceptional position, in that they form acid sulfates with the acid, which neutralizes their basic properties, and causes, as in case of aniline and dimethylaniline, the sulfonic acid group to enter both in meta- and para-position. If, however, only sufficient acid is added to form the acid sulfate and this is heated to a temperature of 180-200 deg. the sulfonic acid group is forced exclusively in para position and a uniform product obtained with a minimum amount of acid.

FIG. 1—SULFONATOR

This process, which is known as the baking-process, is used extensively in the manufacture of amido-sulfonic acids.

If two different groups are present before sulfonation, it will depend on their nature, where the sulfonic acid group enters, but if one of these groups is an amido-group its place will be determined by the other group.

In general, ortho-compounds are sulfonated easier than the corresponding para-compounds. Sulfonations in the benzene-series can be mostly carried out in such a way, that a uniform sulfonation product is obtained, which only has to be separated from the excess of sulfuric acid, which can be done by salting out the sulfonic acid or by neutralizing the mixture with lime and filtering off the precipitated gypsum, after which the lime salt is converted into the sodium salt by means of soda ash.

In the naphthalene-series there is a decided difference in the result of the sulfonations, as a mixture of two or more different sulfonic acids is formed. This is caused by the fact that the sulfonic acid group enters first in a position in which it is often not very strongly bound and, therefore, is partly split off again by hydrolysis, then entering in course of the sulfonation into another position.

The temperature and time of heating have a large influence here, at lower temperature, alpha-sulfonic acids, at high temperature beta-sulfonic acids being

formed, their rate of conversion into each other depending on the time.

As there are eight different positions, in which the sulfonic acid group can enter, the situation is very complicated. When naphthalene is sulfonated both the alpha- and beta-sulfonic acid is formed. On further sulfonation the sulfonic acid group enters by preference in the other ring and with hardly any exceptions it never places itself in ortho-, para- or peri-position to another sulfonic acid group.

Alpha nitro-naphthalene is converted into alpha-nitro-naphthalene 5 sulfonic acid, but as the sulfonation is not easy and the same product can be obtained in a different way, this way of preparation has not found any application.

If an amido- or hydroxyl-group is present, the result of the sulfonation will depend on the place of this group, the naphthols being sulfonated very easily, the naphthylamines with more difficulty. They will be discussed in detail later.

To chlorine in alpha-position the sulfonic acid group enters first in position 4, then in 5 and at higher temperature in positions 6 and 7. The manufacture of these chlorosulfonic acids is not of interest, with the possible exception of alpha-chloronaphthalene 4 sulfonic acid, which by caustic fusion can be converted into Neville-Winther acid, which could be done in practice where chlorine is available at a sufficiently low price.

As the result of the sulfonation is a mixture of different sulfonic acids, it will often be necessary in addition to a separation from the excess acid to carry out a separation of the sulfonic acids, which has to be done by means of the difference in solubility of their salts, by salting out these salts or by their difference in behavior toward diazo-compounds.

We will now discuss the influence of the acid and temperature more in detail.

Sulfuric Acid

Sulfuric acid of the different strengths which are used in the preparation of sulfonic acids, is available in the market. As we have seen, the acid will be diluted by the water formed during the reaction, and the amount for any sulfonation must be such that its concentration, after complete sulfonation, not taking into consideration the amount of sulfonic acid formed, will be high enough to have a sulfonating action on the material.

The sulfonating action of an acid depends in the first place on the degree, to which a product resists sulfonation. All products containing already a group of acid nature, viz., a nitro-, chlorine-, carboxyl- or carbonyl-group, can only be sulfonated with more or less difficulty, and the acid after sulfonation must, therefore, be of a higher concentration, than if the product is sulfonated easily, which is the case with the hydrocarbons and their hydroxyl-compounds.

The alkyl- and amido-compounds are in a medium position.

In the second place the sulfonating action depends on the degree of sulfonation desired, as the sulfonic acid group is of an acid nature and therefore, the molecule resists the entrance of a second and third sulfonic acid group more strongly, so that the concentration of the acid after sulfonation has to be raised accordingly.

It is obvious, that the stronger the acid is, we start with, the smaller will be the required amount, and that it is of advantage for all ordinary sulfonations to use 97-98 per cent sulfuric acid instead of the commercial 66 deg. B. acid, which has a strength of 92-93 per cent.

For instance, for the complete sulfonation of 100 lb. of benzol at 80 deg. C. 415 lb. 92 per cent sulfuric acid have to be taken, whereas, if the 98 per cent acid is

used only 265 lb. are required, in both cases, the concentration after sulfonation falling to 82 per cent, below which benzol is sulfonated only very slowly.

Not only a large amount of acid is saved, but as the excess of acid in the latter case is much smaller, less lime is required for neutralizing the mixture and a smaller bulk of gypsum has to be filtered off, which means in addition a saving in labor.

It would, therefore, be advantageous to use fuming sulfuric acid, of which a still smaller amount would be sufficient, but in the case under consideration this would result in the sulfonation being carried too far, as the first quantities of benzol not only would be mixed with a large excess of highly concentrated acid, but also much heat would be developed by the water liberated on mixing with the strong acid, both of which reasons would cause disulfonic acid to be formed.

To prevent this, it would be necessary to cool the mixture during the first part of the sulfonation, and heating it to the desired temperature after the acid has been sufficiently diluted by the water formed during the reaction, so that the danger of disulfonation has passed.

The foregoing tends to show that there is a lower as well as an upper limit to the concentration of the acid used.

Another way to overcome this difficulty is to start with an acid of ordinary concentration, run in the benzol, and then raise the strength of the acid by adding a sufficient amount of fuming sulfuric acid, as at this stage the dilution will be such as to prevent any disulfonation.

The most economical strength to use will depend in every case on the current price of the available acids. To convert the benzene-sulfonic acid into the disulfonic acid, fuming sulfuric acid containing 20-25 per cent free SO_3 is required, while at the same time the sulfonation has to be carried out at a higher temperature.

To make the trisulfonic acid a larger amount of this acid has to be used and again it would be of advantage to take a stronger acid, were it not that fuming sulfuric acid, containing 30-55 per cent SO_3 , is solid at ordinary temperatures and troublesome to handle. Acids with 55-70 per cent free SO_3 are, however, liquid, and these could be used for reinforcement of the acid, after the sulfonation has been partly completed.

Benzene-trisulfonic acid cannot be sulfonated any further as the sulfonic acid group cannot enter in meta-position to those already present. It is not used for any purpose, as are the naphthalene-trisulfonic acids, which at very high temperature can even be sulfonated to a tetra-sulfonic acid.

Fuming sulfuric acid is also used for those compounds in which the sulfonic acid group enters only with difficulty, such as nitrobenzol, benzoic acid, and amidophenols and for those that have to be sulfonated at low temperatures such as dimethylaniline and many dyes, as the same result can be obtained with a stronger acid at lower temperature as with a weaker acid at higher temperature, providing the temperature has no influence on the nature of the sulfonic acid formed.

In certain cases another point of importance, with regard to the strength of the acid used, has to be taken into consideration, namely, the fact already mentioned, that often the sulfonic acid group enters in a position in which it is not very stable. For instance, in phenol ortho-sulfonic acid, meta-xytol sulfonic acid and meta-cresol sulfonic acid the sulfonic acid group is split off even by boiling with dilute acids, which fact in the last of the three cited cases has found application for the separation of meta and para-cresol. Their mixture is sulfonated, and after diluting the meta-cresol sulfonic acid decomposed by boiling, whereupon the meta-cresol

can be distilled off with steam, the para-cresol sulfonic acid remaining in solution.

This hydrolytic action of the acid also has its influence in the naphthalene-series, where in a number of instances the sulfonic acid group is split off in the position, where it enters first, and afterwards places itself in a more stable position, which is one of the reasons, that in this series, mixtures of different sulfonic acids are formed, the time of heating here having a decided influence on the composition of the mixture. It may, therefore, be necessary to change the strength of acid according to the result desired.

Sulfonations also can be carried out by means of chlorosulfonic acid, which is obtained from sulfur-trioxide and hydrochloric acid gas, or by passing this gas through fuming sulfuric acid and distilling the product. If not used in excess, sulfonic acids are formed and hydrochloric acid liberated, which latter substance, however, introduces serious mechanical difficulties. If used in excess, sulfo-chlorides are formed, the hydroxyl group of the sulfonic acid being replaced by chlorine.

In addition it has the property to direct the sulfonic acid group to a different position than sulfuric acid would and it is in these cases, where a different product can be obtained, that it has found application. Toluol, for instance, by ordinary sulfonation is converted for the greater part into paratoluol sulfonic acid, whereas by the action of chlor-sulfonic acid below 5° C. 60 per cent of the ortho-chlor-sulfonic acid is formed, and which has found a large application in the manufacture of saccharine. In the sulfonation of betanaphthol first the betanaphthol ortho-sulfonic acid is formed which has the sulfonic acid group in position 1, and which under ordinary conditions is immediately transformed into other acids. By dissolving the beta-naphthol in carbon disulfide and submitting it to the action of chlor-sulfonic acid this product, however, can be prepared.

It has been suggested to replace fuming sulfuric acid by a mixture of sulfuric acid and pyrosulfate, but as this introduces a large amount of sodium bisulfate in the sulfonation-mixture, it is not done to any great extent.

There is a class of sulfonations, to which here properly may be called attention, those by means of sodium bisulfite. Amido-compounds form sulfurous ethers with sodium bisulfite, which under certain conditions can be converted into sulfaminic acids and further into amido-sulfonic acids, the sulfonic acid group placing itself in para-position to the amido group, or occasionally in ortho-position. In practice, the starting point for these sulfonations are nitro- or nitroso-compounds, which first are reduced by the bisulfite to hydroxylamine compounds, which also are able to form sulfaminic acids. This reaction has enabled the manufacture of an important intermediate, 1-2 amido naphthol 4 sulfonic acid from beta-naphthol the latter being first converted into nitrosonaphthol.

Temperature and Time

As already stated, the temperature during the sulfonation is of the utmost importance, not only that the nature of the sulfonic acid depends on it, but also, that it influences the result of the sulfonation in connection with the amount and concentration of the acid. If a product is sulfonated without difficulty, there is danger that more than one sulfonic acid group enters the molecule and the higher the temperature is, the greater this danger, as the action of the acid will be stronger at more elevated temperature, which may make it necessary to cool the mixture, especially in the beginning of the operation, while in many other cases heating is required

to complete the sulfonation. On the other hand, the acid at a higher temperature may decompose part of the product and cause a loss of material. The temperature, therefore, varies according to conditions, ranging all the way from 0 deg. to 200 deg. C.

Since it is most economical to use as concentrated an acid as possible, unless it has an influence on the nature of the sulfonation product the temperature will not be a deciding factor, and will be determined by the strength of acid. In order not to use an excessive amount of acid, the temperature is raised at the end of the operation sufficiently high to complete the sulfonation, time also being saved in this way and the capacity of the apparatus increased correspondingly. In cases where the acid has a corrosive action on the substance sulfonated at higher temperatures, which would impair the quality or the yield of the product, as for example in the sulfonation of beta-naphthol and many dyes, the amount and strength of the acid has to be chosen in accordance with the maximum temperature to which the mixture can be heated.

The heat developed by the reaction itself is not great, so that there is little danger of losing control over the operations as in case of nitrations and reductions, the only result here being that the sulfonation will be carried too far and the material may be partly decomposed.

In the benzene-series, the temperature has little influence on the nature of the product obtained, with the exception of the phenol-sulfonic acids, where the para-compound is almost exclusively formed at higher temperature and in the sulfonation of benzol. Benzene-sulfonic acid is converted up to 90 per cent into the meta-disulfonic acid, the amount of the para-compound which is formed as a by-product, increasing at higher temperature and on longer heating.

It is in the naphthalene-series, that the result of the sulfonation depends entirely on the temperature, the amount and concentration of the acid simply determining the degree of sulfonation.

When naphthalene is sulfonated, a mixture of alpha- and beta-sulfonic acid is formed, and it is not possible to obtain one of these acids exclusively for the reasons mentioned before. At 80 deg. about 80 per cent of the alpha-sulfonic acid is obtained, while at 160 deg. about 85 per cent of the beta-sulfonic acid is formed, the equilibrium gradually changing from one to the other at intermediate temperatures. The old way of preparing the beta-sulfonic acid was to heat the acid to 120-130 deg., add the naphthalene, heat the mixture at 160 deg. for a sufficiently long time to convert the alpha-sulfonic acid into the beta-sulfonic acid and then raise the temperature to 175-180 deg. to drive out the water and complete the sulfonation, which allowed a material saving to be made in the amount of acid required. On the other hand this high temperature caused a small amount of the sulfonic acid to be converted into sultone, while part of the naphthalene escaped sulfonation, as it evaporated with the water.

It is therefore, a great advantage to follow the process, described by Witt, which consists in fusing the naphthalene, heating it to 160 deg. and running in the acid slowly, keeping the temperature throughout at 160 deg. The amount of acid required is larger, as the water is not driven off, but no sultone is formed and no naphthalene escapes sulfonation, so that a higher yield is obtained of a product of better quality.

Another great advantage over the old process is, that the sulfonation is carried out at a uniform temperature of 160 deg. C., so that the maximum amount of beta-sulfonic acid is formed immediately, and no time has to be wasted for converting the alpha-sulfonic acid into the beta-sulfonic acid. It is this feature of the process

which makes it profitable to apply it also in the manufacture of the higher sulfonic acids of naphthalene.

On further sulfonation of alpha-naphthalene-sulfonic acid at lower temperature, the sulfonic acid group enters again in alpha-position, but in the other ring and as position 8 is protected, we will obtain the 1-5 disulfonic acid. In this acid the two remaining alpha-positions are in para-position to those already occupied, so that a third and fourth sulfonic acid group will have to enter in beta-position, of which position 2 and 6 again are protected, being in ortho-position to those taken up. We, therefore, obtain the 1-3-5 naphthalene-trisulfonic acid and 1-3-5-7 tetrasulfonic acid.

If alpha-naphthalene sulfonic acid is sulfonated at a little higher temperature, the sulfonic acid group also will place itself in beta-position, and 1-6 disulfonic acid being obtained, which can further be converted into the 1-3-6 trisulfonic acid and the 1-3-6-8 tetrasulfonic acid.

These last two are the only ones that can be formed, and we, therefore, would obtain a uniform sulfonation product if it was not that the 1-6 disulfonic acid will always be contaminated with the 1-5 disulfonic acid, which is formed at the same time and with the disulfonic acid, obtained from the small amount of beta-sulfonic acid, present in the alpha-acid.

To purify the 1-6 disulfonic acid first would be tedious and it is generally preferred to postpone any purification until the ultimate product has been prepared.

In the beta-sulfonic acid the sulfonic acid at lower temperature can enter into alpha-position, which will give us the 1-6 disulfonic acid, at higher temperature into the beta position, when we will get a mixture of the 2-6 and 2-7 disulfonic acids.

All these disulfonic acids are convertible into each other, the 2-6 acid being the most stable at the highest temperature. Both the 1-6 and 2-7 disulfonic acids can be converted into the 1-3-6 trisulfonic acid and the 1-3-6-8 tetrasulfonic acid, while the 2-6 disulfonic acid forms the 1-3-7 trisulfonic acid, which like the 1-3-5 trisulfonic acid goes over into the 1-3-5-7 tetrasulfonic acid. In case of the 2-6 and 2-7 disulfonic acids, the two remaining beta-positions are protected and another sulfonic acid group, therefore, has to enter in alpha-position, even at higher temperature. In the 1-3-6-8 tetrasulfonic acid we have an exception to the rules, in that the sulfonic acid group places itself in position 8, or in peri-position to another sulfonic acid group.

The preceding can be readily followed with the aid of the diagram below:

As pointed out Witt's process here also will give more favorable results, as, for instance, the beta-sulfonic acid can first be prepared, and converted at 160 deg. into the disulfonic acid by an additional amount of acid, the maximum amount of 2-7 disulfonic acid then being obtained, which subsequently can be converted into the 1-3-6 trisulfonic acid by reinforcing the acid.

The naphthols are sulfonated very easily, and care has to be taken that the temperature is not carried above

the point where the corrosive action of the acid will become noticeable.

Sulfonation of alpha-naphthol yields a mixture of the 2 and 4 sulfonic acids, and the 2-4 disulfonic acid, while at a little higher temperature the 2-4-7 trisulfonic acid is formed with a small amount of 2-4-6 trisulfonic acid. The sulfonic acid groups in positions 2 and 4 are not very strongly bound, which causes the 2-7 and 4-7 disulfonic acids also to appear in the sulfonation-mixture. If the hydroxyl-group is protected, however, which can be done by converting the alpha-naphthol into alpha-naphthol carbonate the sulfonation will go much more smoothly, first the 4 sulfonic acid being obtained, then a mixture of the 4-6 and 4-7 disulfonic acids, in analogy to the sulfonation of alpha-naphthylamine. It appears that the sulfonic acid group in alpha-naphthol derivatives never enters in position 3, 5 or 8.

In beta-naphthol the sulfonic acid group first enters in position 1, in which it is so unstable that it is immediately converted into the 8 sulfonic acid or Croceine acid which in its turn at higher temperature goes over into the 6 sulfonic acid or Schaeffer acid. On further sulfonation these two acids form the 6-8 disulfonic acid or G-acid, and the 3-6 disulfonic acid or R-acid respectively, both of which are generally prepared by direct sulfonation of beta-naphthol at different temperatures and both of which ultimately go over into the 3-6-8 trisulfonic acid. The beta-naphthol 7 sulfonic acid can be sulfonated to a mixture of the 1-7 and 3-7 disulfonic acids, which can be converted into the 1-3-7 trisulfonic acid and ultimately into the 1-3-6-7 tetrasulfonic acid, which is the only case in which the sulfonic acid group enters into orthoposition to another one.

Alpha-naphthylamine is converted into a mixture of the 4 and 5 sulfonic acids, the latter being obtained in greater amount with fuming sulfuric acid at a low temperature, and the former most at higher temperature, while at the same time a small amount of the 6 sulfonic acid is formed. The 4 sulfonic acid or naphthionic acid, which is the most important, is made preferably according to the baking-process. By further sulfonation it goes over into a mixture of the 4-6 and 4-7 disulfonic acids, generally known as Dahl's acids II and III, the 5 sulfonic acid into a mixture of the 2-5 and 5-7 sulfonic acids, both of which can be converted into the 2-5-7 trisulfonic acid.

In the other alpha-naphthylamine sulfonic acids, which can mostly be obtained by nitration and reduction of the naphthalene-sulfonic acids, a second sulfonic acid group enters in position 4 or 5, a third one in position 2 or 7, as can be seen from the following table:

Sulf. Acid	Disulf. Acid	Trisulf. Acid
2	2-5	2-5-7
3	3-5	3-5-7
6	4-6	2-4-6
7	4-7	2-4-7
8	4-8	2-4-8

The alpha-naphthylamine 5-7 disulfonic acid, which is of technical importance can be prepared by sulfonation of alpha-acet-naphthalide, the acetyl-group protecting position 2 and 4, which causes the sulfonic acid group to enter exclusively in position 5, the 5 sulfonic acid then being converted into the 5-7 disulfonic acid only.

The sulfonation of beta-naphthylamine is very complicated, a mixture of the 5, 6, 7 and 8 sulfonic acids being formed, the 5 and 8 sulfonic acid to a greater degree at lower temperature, being alpha-sulphonic acids, the others at higher temperature. It is hardly possi-

ble to prepare them in a pure state, except the 5 sulfonic acid, which can be obtained by sulfonation of beta-acetnaphthalide. The others are preferably made by replacing the hydroxyl-group by the amido-group in beta-naphthol sulfonic acids by means of ammonia. A second sulfonic acid group enters often in position, in which position, however, it is not stable, and may also enter in the same ring in meta position to the first one.

Caustic Fusions

Closely connected with the sulfonations are the caustic fusions, which convert the sulfonic acids into hydroxyl-compounds by fusing them with caustic soda. The sulfonic acid, probably under influence of the caustic soda, first goes over into an ester of sulfurous acid, which subsequently is decomposed into a phenolic body and sodium sulfite. This reaction takes place only at a high temperature, which makes it necessary to use an excess of caustic soda to keep the mixture in a liquid state at this temperature, but as many organic compounds are easily oxidized in the presence of caustic soda at a high temperature, especially if there are any amido-groups present in the molecule, a considerable amount of material is lost through oxidation and the yield leaves much to be desired. This can often be improved by carrying out the caustic fusion with water

these higher sulfonic acids the sulfonic acid groups are not all at once replaced, benzene meta-disulfonic acid, for instance, first being converted into phenol meta-sulfonic acid, then into meta-dioxybenzol or resorcin. A peculiarity of the caustic fusions is that sometimes the hydroxyl-group not always enters in the same position as the sulfonic acid, which it replaces, which can be illustrated by the fact that benzene-ortho- and para-disulfonic acid by fusion with caustic soda also are converted into resorcin.

In the naphthalene-series the sulfonic acid groups in alpha-position are, as a rule, easier replaced by the hydroxyl-group than those in beta-position, which has made the manufacture of amido-naphthol sulfonic acids from naphthylamine sulfonic acids possible. Especially those of 1-8 amido-naphthol such as H-acid and 2-8 amido-naphthol, such as Gamma acid, are of great practical importance. The replacement of a sulfonic acid group in alpha-position is especially easy, if it is in position 8 to an amido-group or in meta-position to another sulfonic acid group. If these fusions of naphthylamine-sulfonic acid are carried out in the presence of water it must be taken into consideration that the amido-group also may be replaced by the hydroxyl-group, due to the hydrolytic action of the water, which may cause the 1-8 amido-naphthol 3-6 disulfonic acid or H-acid, for example, to be converted into 1-8 dioxy-naphthalene 3-6 disulfonic acid or chromotropic acid. A few of the naphthalene sulfonic acids also are converted into naphthol-sulfonic acids by caustic fusion.

Of the fact, that the material can be oxidized in the presence of caustic soda advantage has been taken in the manufacture of alizarine and other anthracene dyes. Alizarine is made by sulfonation of anthraquinone and caustic fusion of the sulfonic acid, the mono-sulfonic acid hereby being converted into dioxy-anthraquinone or alizarine. Usually the oxygen needed for the oxidation is not supplied by the air alone, but partly by an oxidizing agent, such as sodium chlorate or sodium nitrate.

Not only the sulfonic acid group but also the chlorine-group under certain conditions can be replaced by the hydroxyl-group. If this could be done in chlorbenzol we would have a very simple process for the manufacture of carboic acid, but the temperature at which the chlorine-group here is replaced is so high that the resulting pressure is too high to make the process of commercial interest. If any acid groups are present in the molecule, however, the conversion becomes easier and can be carried out under workable conditions. So, for instance, in ortho- and para-nitrochlorbenzol, the chlorine is made removable by the presence of the nitro-group, making it possible to convert them into ortho- and para-nitrophenol. If two nitro-groups are present, as in dinitrochlorbenzol, the conversion is so easy that boiling with caustic soda is already sufficient to form dinitrophenol. In the naphthalene-series we find an example in alpha-chloronaphthalene 4 sulfonic acid, from which alpha-naphthol 4 sulfonic acid, an important intermediate, may be prepared.

That the sulfonic acid group is not always replaced, we can see in the case of naphthionic acid, which by the action of concentrated caustic soda solution under pressure, can be converted into alpha-naphthol 4 sulfonic acid, the amido-group being replaced instead of the sulfonic acid group. The conversion is not easy, however, and the process has been practically abandoned.

To obtain the hydroxyl-compounds in a pure state, the fusion mixture is dissolved in water and the solution acidulated, the acidulation being carried only so

FIG. 2—FUSION KETTLE

in autoclaves under pressure, which allows the amount of caustic soda to be cut down materially and prevents oxidation. The disadvantages of using autoclaves is their limited capacity and the long time required for their operation, wherefore they are used only in such cases where the materials are more expensive or the amount of caustic soda required for fusion in open kettles is excessive.

In the manufacture of carboic acid from benzene-sulfonic acid and beta-naphthol from beta-naphthalene sulfonic acid, which are both manufactured in very large quantities, the use of autoclaves, therefore, is not practicable. These two products, being mono-sulfonic acids the excess of caustic soda required is not large, it having also been found in the case of carboic acid that pressure-fusion has no favorable influence on the yield. In the case of di- and trisulfonic acids, however, a much larger excess of caustic soda has to be used, and here generally the use of autoclaves will be preferred. These products at the same time are the more expensive ones, and mostly not prepared in such large amounts. In

far that the sulfite is converted into bisulfite. If the hydroxyl-compound is soluble, as is often the case, it can then be precipitated by addition of salt to the solution. Resorcline forms an exception, in that it is soluble in water and cannot be salted out. To obtain it in a pure form, the solution is extracted with an organic solvent and the crude resorcline distilled in vacuum.

Application

The sulfonic acids of benzol are only manufactured as intermediate products in the production of phenol and resorcline, into which the mono- and disulfonic acid respectively are converted by caustic fusion. The first is only used to a small extent in the preparation of dyes, but in enormous quantities as an antiseptic and in the manufacture of artificial resins and picric acid. Its production during the year 1916 was estimated at 10,000 tons. Nitroso-phenol, which enters in the manufacture of a few dyes, can be made from phenol by the action of sodium nitrite. Salicylic acid, which also can be made from phenol, has found application both in the dyestuff industry and for medicinal purposes, as has resorcline. To make picric acid from phenol it is necessary to sulfonate the phenol first, and it is possible to make it from either the mono-sulfonic acid or the trisulfonic acid. The first is treated with a large excess of nitric acid and does not give a very good yield, while the second, which has to be made with fuming sulfuric acid and, therefore, is more expensive, can be converted into picric acid with only a slight excess of nitric acid or its equivalent in sodium nitrate and gives a better yield.

Ortho-toluol sulfochloride, which is formed by the action of chlorsulfonic acid on toluol, is the starting point in the manufacture of saccharine. The para-compound is obtained as a by-product and has found application in the form of its methyl- or ethyl-ester as an excellent alkylating agent.

The sulfonic acid of nitrobenzol is converted by reduction into metanilic acid, which is mainly used in the manufacture of metanil yellow. The metanilic acid by caustic fusion gives meta-amidophenol, one of the intermediate products in the preparation of the Rhodamine dyes. The alkyl compounds of meta-amido phenol, which also are used for this purpose, are obtained by sulfonation of the alkyl-compounds of aniline with fuming sulfuric acid at low temperature, followed by caustic fusion.

Para-nitrotoluol sulfonic acid is the basic material for the manufacture of the stilbene-dyes, chrysophenine and brilliant-yellow. Of other nitro-sulfonic acids those of nitrochlorbenzol deserve attention. The chlorine-group here is unstable and can be replaced by the hydroxyl-group by means of caustic soda. On reduction, we then can obtain the amidophenol sulfonic acids, the ortho-amidophenol sulfonic acid giving important chrome-dyes of excellent fastness. In nitrochlorbenzol itself, the chlorine-group can also be replaced by the hydroxyl-group, as we have seen. Of the nitrophenols formed, the para compound can be used for manufacturing para-amidophenol, the ortho compound for anisidine and dianisidine. The nitrochlorbenzol-sulfonic acids can also be converted into nitraniline-sulfonic acids, from which a few lake-dyes are derived.

The sulfonic acids of amido-compounds, such as aniline, toluidine, xyldine, amidoazobenzol, meta-phenylene diamine and meta-tolylene diamine are intermediate products for the manufacture of many azo dyes. Ethyl-benzylaniline sulfonic acid is more used for triphenylmethane-dyes.

Naphthalene-sulfonic acids are only intermediate products in the manufacture of other naphthalene-compounds. By caustic fusion they can be converted

into naphthols and naphthol sulfonic acids. The most important one is the beta-naphthalene sulfonic acid, the first stage in the preparation of beta-naphthol, which is used in enormous quantities for making beta-naphthylamine, beta-naphthol sulfonic acids, para red and many other dyes. Alpha-naphthol generally is not made from alpha-naphthalene sulfonic acid, but from alpha-naphthylamine sulfate by heating this with water under pressure. Its application is limited, as we have seen that on sulfonation an inseparable mixture of sulfonic acids is formed. This mixture on nitration can be converted into naphthol yellow, the most important dye made from alpha-naphthol. Other naphthol-sulfonic acids, obtained from naphthalene-sulfonic acids, are Cleve's alpha-naphthol 5 sulfonic acid, alpha-naphthol 3-6 sulfonic acid GR and beta-naphthol 7 sulfonic acid F. The first two are used for azo-dyes, the last one for preparing a blue shade of para-red and for making beta-naphthylamine 7 sulfonic acid.

By nitration, followed by reduction, the naphthalene-sulfonic acids can be converted into alpha-naphthylamine sulfonic acids. The most important are alpha naphthylamine 8 sulfonic acid from the alpha-sulfonic acid, the 5 sulfonic acid or Laurent acid being obtained as a by-product; a mixture of Cleve's alpha-naphthylamine 6 and 7 sulfonic acid from the beta-sulfonic acid and Freund's alpha-naphthylamine 3-6 disulfonic acid from the 2-7 disulfonic acid, all of which are used in the manufacture of azo-dyes. Others are not used as such, but only for the preparation of other intermediate products. The amido-group, for instance, can by different means be replaced by the hydroxyl-group, thereby forming alpha-naphthol sulfonic acids, which is done for the preparation of alpha-naphthol 3-8, and 4-8 disulfonic acids and the 3-6-8 trisulfonic acid.

Of the alpha-naphthylamine sulfonic acids, obtainable by direct sulfonation, naphthionic acid is the most important, and used in large quantities for preparing azo-dyes and in the manufacture of Neville Winther's alpha naphthol 4 sulfonic acid. Laurent's alpha-naphthylamine 5 sulfonic acid is not made by direct sulfonation, as it then is not pure, and it is obtained in sufficient quantities as a by-product in the manufacture of the 8 sulfonic acid.

The beta-naphthylamine sulfonic acids, as already mentioned, can only be prepared in a pure state from the beta-naphthol sulfonic acids by means of ammonia. All naphthylamine di and trisulfonic acids can be converted into amidonaphthol sulfonic acids by caustic fusion. The most important is H acid or 1-8 amido-naphthol 3-6 sulfonic acid, obtained by nitration and reduction of naphthalene 1-3-6 trisulfonic acid followed by caustic fusion. Gamma acid or 2-8 amido-naphthol 6 sulfonic acid is next in importance and can be prepared by converting beta-naphthol 6-8 disulfonic acid G into the corresponding beta-naphthylamine compound and fusing this with caustic soda. Others are 1-8 amido-naphthol 4 sulfonic acid S, 2-4 disulfonic acid S, and 4-6 disulfonic acid K, 1-5 amido-naphthol 7 sulfonic acid M, 2-7 amido-naphthol 7 sulfonic acid J, and 2-8 amido-naphthol 3-6 disulfonic acid RR, which all are made from the corresponding naphthylamine sulfonic acids. The 1-2 amido-naphthol 4 sulfonic acid is prepared from nitroso beta-naphthol with sodium sulfite, and the amido and hydroxyl group being in ortho position to each other, it gives valuable chrome dyes.

The beta-naphthol sulfonic acids, which have been mentioned, also are of great importance. We obtain a mixture of the Croceine and Schaeffer acid or of the R and G acid, of which the Croceine and G acid and their salts are much more soluble than the other two, of which property we can make use for their separation, in that the salts of Schaeffer and R acid can be pre-

precipitated by adding salt to their solutions. The precipitate can be washed with salt-solution free of the other component acid which separation is quite satisfactory for preparing Schaeffer and R salt. The precipitation, however, is not complete and the other two acids can, therefore, not be purified in this way. As they both contain a sulfonic acid group in position 8, they combine much slower with certain diazo-compounds, especially diazo-xytol, than Schaeffer and R salt. Their purification is carried out by combining these two acids with diazo-xytol or another suitable diazo-compound and salting out the dye found, the pure Croceine or G salt remaining in the mother-liquor, from which they can be obtained by evaporation.

Further sulfonic acids of the naphthalene-series are 1-8 dioxy-naphthalene 3-6 disulfonic acid or chromotropic acid, obtained by replacing two sulfonic acid groups in 1-3-6-8 naphthalene tetra sulfonic acid with caustic soda; or by fusing alpha-naphthol 3-6-8 trisulfonic acid with caustic soda; 1-8 dioxy-naphthalene 4 sulfonic acid, made by replacing the amido by the hydroxyl-group in 1-8 amido-naphthol 4 sulfonic acid, and the sulfonic acids of dioxy-naphthoic acid. These are prepared by converting alpha- or beta-naphthol into the oxy-naphthoic acid in the same way as salicylic acid is made from phenol, sulfonating this product and fusing the disulfonic acid with caustic soda.

All these sulfonic acids of the naphthalene-series are almost exclusively used in the manufacture of azo-dyes.

Sulfonations and caustic fusions are also carried out to a large extent in the manufacture of many anthracene-dyes, the simplest of which is alizarine, made by sulfonation of anthraquinone and caustic fusion of the sulfonic acid in the presence of an oxydizing agent, whereby dioxyanthraquinone is formed, which is alizarine, the well-known substitute for Madder.

Dyes are often sulfonated to increase their solubility or improve their quality otherwise. The best known examples are alkali blue, soluble blue, water blue, patent blue, primuline, induline and nigrosine.

Apparatus

Sulfonations are carried out in kettles of acid-proof cast iron, provided with an agitator. With the exception of benzol and toluol, all materials to be sulfonated in the ordinary way are solids and as the sulfonic acids are all soluble in the excess acid the sulfonation mixture is homogeneous, so that a simple agitator of the propeller or horseshoe type will be sufficient. In the case of benzol, however, the agitation has to be very thorough, as benzol is immiscible with and very much lighter than sulfuric acid. The best type of agitator is a high speed propeller placed inside a cylinder, which is perforated at the bottom. The propeller is run in such a direction that it takes the benzol down from the surface, mixes it with the acid and forces the mixture through the openings at the bottom and causes it to rise along the sides of the kettle. In general, sulfonations are very simple, and can be carried out without difficulty, the acid being run into the kettle, the material being added gradually and the mixture being kept at the desired temperature until the sulfonation has been completed.

As we have seen, sometimes the mixture is cooled during the first part of the operation and heated afterward, generally by means of steam, which can be easily done by providing the sulfonating kettle with a jacket. If steam-pressure is not sufficient to reach the desired temperature, the heating can be done by means of an oil-bath, which is heated directly. Wherever a battery of kettles has to be heated, it is more economical to circulate oil through the jackets of the kettles and have a

central heating system. If a sulfonation at high temperature is followed by a nitration, the sulfonating kettle has to be oil-heated and the mixture has to be transferred to a second kettle, in which it can be cooled and nitrated. It would be of advantage to carry the operation through in one kettle, which can be done if the kettle has a heating-coil cast in, through which first pressure-water is circulated which, after the sulfonation is complete, is gradually replaced by cold water.

The sulfonation of amido-compounds is often carried out, as already mentioned, by heating the acid sulfate at a temperature of about 200 deg., which is done in an oven in which this acid sulfate is placed in trays on shelves, which are heated by means of furnace-gases. The operation can be considerably facilitated by conducting the operation in a vacuum.

The separation of the excess sulfuric acid from the sulfonic acid can be done in three different ways. If the sulfonic acid is not soluble in dilute acid, as in case of beta-naphthalene sulfonic acid the sulfonation mixture can be diluted with water, which causes the sulfonic acid to precipitate. If a large excess of sulfuric acid is used, the sulfonic acid can often be precipitated by adding salt to the diluted sulfonation mixture, which sometimes effects a separation of sulf. acids of different solubility at the same time. In both cases large amounts of dilute acid have to be handled and acid-proof filtering devices, which are yet far from perfect, have to be used. If the sulfonic acid, and its salts, however, are too soluble under these conditions, or if it is preferred not to handle any acid liquors, the sulfonation mixture can be neutralized with lime, the sulfuric acid being precipitated as gypsum, which can be filtered off in ordinary filterpresses and washed. The sulfonic acid then is obtained in form of its lime salt, which is converted into the sodium salt by means of soda ash, as the lime salts generally cannot be used as such. If a caustic fusion follows the sulfonation, the lime would cause the fusion-mixture to become very thick, and a large excess of caustic soda would be required. Many sulfonic acids are used directly in the manufacture of dyes, especially azo-dyes, and here the lime might often cause the dye to precipitate as a lime salt, insoluble in water.

The sodium salts of the sulfonic acids are soluble in water, which solution sometimes can be used immediately in the manufacture of dyes. If a mixture of sulfonic acids is formed, it may be desirable to separate them, before they are used further, which can often be effected by salting out the sodium salt or the acid sodium salt of the least soluble sulfonic acid. For all

FIG. 3—ATMOSPHERIC DRUM DRYER

these operations, following a sulfonation, only wooden or lead-lined tanks and filtering apparatus are required.

In the manufacture of carbolic acid the sodium sulfonate of benzol is obtained in solution, which must be evaporated to dryness. As enormous amounts of this product are produced at the same time, it is important to do this in the most economical way, which consists in concentrating the solution in a vacuum-evaporator and evaporating the concentrated solution to dryness in one operation on an atmospheric drum dryer, thereby bringing down the cost of this operation to a minimum. This apparatus can be used to advantage in all similar cases wherever the sodium salt of a sulfonic acid has to be prepared in the dry state.

Caustic fusions are carried out either in open cast iron kettles, in which the caustic soda is fused and the sodium sulfonate gradually added or in autoclaves under pressure. For pressures up to 500 lb. these autoclaves can be made of cast iron, but for higher pressures they have to be made of cast steel. Both autoclaves and fusion kettles are provided with an agitator and are placed in a furnace, which is heated by oil or gas, as the temperature to which the mixture is heated is often above 300 deg. C. When the fusion is finished the mixture is dissolved in water. The contents of an autoclave are sufficiently liquid to blow them into water by air-pressure, but in case open kettles are used the mixture is generally ladled out, allowed to solidify and then dissolved. It has been tried to provide these fusion kettles with a bottom-outlet, in order to run out the mixture, but as it is difficult to keep these bottom openings tightly closed and as they burn out gradually, they have not given much satisfaction. The operations following a caustic fusion, consisting in acidulating the solution of the fusion mixture, separating out the hydroxyl-compound if necessary, and filtering this off, requires only wooden tanks and simple filtering devices. Carbolic acid separates out as a liquid, and the acidulation is, therefore, carried out in iron tanks with conical bottom. The soluble hydroxyl compounds can be purified by recrystallization. Phenol, alpha- and betanaphthol are purified by distillation, the latter two in vacuum.

50 Church St., New York City.

Synopsis of Recent Metallurgical and Chemical Literature

Refrigeration

The Steam Jet Refrigerating Machine.—In the *Electric Journal* for January, J. C. BERTSCH of the Westinghouse Machine Co., describes the Leblanc refrigerating machine which produces refrigeration by the evaporation of water. The process is an old one, strictly speaking, but its successful commercial development is comparatively recent. To Maurice Leblanc, of France, is given the credit for perfecting this machine, and developing the high vacuum-producing and vapor displacing devices known as the Westinghouse-Leblanc ejector and air pump. With the use of these appliances, the refrigerating process consists simply of the evaporation of a part of the water contained in the substance to be cooled or concentrated under a very high vacuum, which is produced by steam jets; the condensation of the vapor and working steam and the removal of the air and condensate from the condenser by special pumps.

A diagram of the apparatus as used for general purposes is shown in Fig. 1. For temperatures above 35 deg. F., as required for air conditioning plants, drinking water systems, rubber rolls, etc., water alone

FIG. 1—TYPICAL ARRANGEMENT OF LEBLANC REFRIGERATING MACHINE

is used as the cold carrier, but for temperatures below 35 deg. F., salt brine is used as carrier.

The evaporator is divided by a cylindrical partition into a brine and vapor space, the former has near the top a perforated horizontal partition as shown, through which the warm brine from the cooling coils is returned to the evaporator in the form of a spray. The make up regulator, consisting of a float valve, controls automatically the amount of makeup water needed to replenish the water lost by evaporation.

The evaporation under vacuum and subsequent cooling is produced by the steam ejector shown at the top of the vapor space. This is the most important part of the apparatus, as it maintains a high vacuum and removes the great quantities of vapor necessary. It is made up a large number of small De Laval steam nozzles, which give a high velocity. The condenser is a steam condenser as commonly used in connection with turbines and steam engines. A cooling tower is very desirable. A specially designed Leblanc air pump is used for removing the air in the condensed water. For the circulation of the cold brine a cold water pump (centrifugal type) is used as shown. The entire absence of chemicals, the automatic operation, and the limitation of the moving parts to a few centrifugal pumps, make very little attention necessary. Actual tests on a 60-ton machine in a rubber plant showed a cost per ton of refrigeration of \$0.304 to \$0.334, producing 72-79 tons per day. Besides chemical and sugar works, the machine is specially suited for marine works.

Iron and Steel

Grain-growth in Low Carbon Steel.—At the eighty-first meeting of the Faraday Society on Dec. 18, 1916, in London, a paper on "Grain-growth in Deformed and Annealed Low Carbon Steel," presented by RALPH H. SHERRY of Detroit, U. S. A., was read by Sir Robert Hadfield for the author.

Coarse crystallization or grain-growth in pure iron and low-carbon steels permanently deformed and annealed has from time to time caused no little difficulty to workers in sheet, wire, cold-drawn bar and pressings of these materials. The present paper, based on an extended investigation, explains the conditions under which grain-growth occurs.

The author summarizes his results as follows:

1. Grain-growth in low-carbon steel will be produced by permanent deformation of the metal within certain limits, followed by annealing within certain temperature ranges.
2. The greater the amount of strain within these deformation limits, the smaller will be the grain-size produced by annealing.
3. The limits of the annealing range within which

this grain-growth will be produced are 650 deg. and 900 deg. C.

4. When the strain is less than a certain or "critical" amount, the annealing range seems to be limited by the thermal critical points at about 690 deg. and 780 deg. C.

5. The most practical standard by which to measure the permanent deformation seems to be the reduction of area. No grain-growth occurs following a reduction of area of less than about 7 per cent or more than about 25 to 30 per cent. The "critical" strain seems to be marked by a reduction of area of about 9 per cent.

6. The refining action taking place at about 780 deg. C. is a further indication of the presence of a thermal critical point at this temperature.

7. The presence of carbon causes a suppression of grain-growth, an effect which, while negligible when the carbon content is low, is very pronounced when the steel contains 0.15 per cent or more. No noticeable grain-growth was found to occur in steels which were uniformly above 0.18 per cent in carbon content.

Grain-growth can therefore be avoided by the application of comparatively heavy work to the metal before annealing, or by proper control of the annealing temperature. If the cold-worked metal is not annealed no grain-growth can occur.

The president, Sir Robert Hadfield, in presenting the paper, said that experiments he was carrying out showed that far below 300 deg. C. phenomena occurred in steel showing it not to be in a quiescent state. This fact was not properly appreciated, and it might explain why breakages often took place long after the material had been hardened. He wished Mr. Sherry had not confined himself to only one type of steel.

Dr. W. Rosenhain said Mr. Sherry's paper gave a new significance to the importance of "ghosts" in mild steel. In these relatively carbonaceous areas grain-growth could occur, and if this was facilitated by phosphorus the handling of mild steel needed careful watching. The annealing point recommended (650 deg. C.) was only safe in a material that did not rely on carbon content for the greater portion of its strength. It could be inferred from the paper that the theory of the existence of a thermal critical point at about 780 deg. was far from dead.

Specific Resistance of Iron.—At the eighty-first meeting of the Faraday Society in London, Dec. 18, 1916, Prof. E. D. CAMPBELL of the University of Michigan, U. S. A., presented a paper entitled "Do Equiatomic Solutions in Iron Possess Equal Resistances?" The following is an abstract of the paper, which was read for the author by Sir Robert Hadfield:

The conception of steel as a solid solution has long suggested a relationship between its chemical composition and resistance. Le Chatelier's work in 1898 indicated that equiatomic concentrations of carbon as hardening carbon and silicon exerted practically equal effect on the specific resistance, while that due to manganese was only about five-sevenths as great, that of nickel three-sevenths to five-sevenths as great, and that due to chromium, tungsten, and molybdenum was very slight. Benedicks, in 1902, laid down the general law that equiatomic solid solutions in iron possess equal resistances.

The experimental work of Arnold has shown the assumptions underlying Benedicks' law to be untenable, and the object of the author's experimental work was to seek a more satisfactory hypothesis. The experiments, which are described in the paper, were carried out on seven steels of varying compositions, and their specific resistances were measured in both the hardened and annealed states. The deviations from the calculated values cannot be explained on Benedicks' as-

sumption, but they suggest that it is the *molecular* concentration of the *carbides* in solid solution and not the *atomic* concentration of the *carbon* which determines the influence on the specific resistance exerted by such solutes.

The almost constant value of the absolute increase in specific resistance with increased temperature, this increase differing very slightly from that of pure iron, would indicate that the increase is almost wholly due to the increase in specific resistance of the solvent, while that component of the total specific resistance due to the solutes in solid solution is only slightly affected by the temperature at which the specific measurements are made.

Tungsten

Manufacture of Tungsten in England.—When the war broke out the manufacturers of high-speed tool steel in England found themselves in much the same position as the users of dyestuffs. The *Engineer* (London) states that, following a Government inquiry into the manufacture of tungsten, a committee was formed of representatives of leading steel makers and thirty-one firms took shares in a company which was formed, called High Speed Steel Alloys, Ltd. The erection of the works was commenced about the end of 1914, and by July, 1915, the production was begun. In September, 1915, the British Government took control of all wolfram ore within the British empire and divided it among the makers of tungsten and ferro-tungsten. To assist in increasing the output of ore within the empire the company purchased mines in Burma, which have been placed under the control of Dr. W. R. Jones, who was formerly in charge of the Indian Survey. Ore is also obtained from Australia, and it is hoped that before long South Africa will be another source of supply. The works of the company are now in full operation and are using the following process: The ore is crushed, ground, screened and mixed with soda. A magnetic separator is used for separating tin ore from the tungsten ore. The mixed ore and soda are roasted in coal-fired reverberatories, requiring two to three hours. The furnace product is boiled with water and the tungstate of soda dissolved. The solution is then filtered and the filtrate containing the tungsten is treated with hydrochloric acid, when tungstic oxide precipitates. This is filtered off and dried, mixed with powdered anthracite coal and placed in crucibles, which are heated in coke stoves. The last-named process will, however, shortly be improved upon as a new continuous furnace, heated by gas from two Wilson bituminous gas producers, is now being erected. The reduced metal is then washed in dish-shaped trays and dried, yielding the final product in the shape of a fine chocolate colored powder of 98 to 99 per cent purity. This is packed in tin-lined wooden boxes containing about 200 lb. ready for delivery.

Refractories

A Carbon Tube Furnace for Testing Refractories.—At the eighty-first meeting of the Faraday Society, held in London, Dec. 18, 1916, EZER GRIFFITHS and EDGAR A. GRIFFITHS of the National Physical Laboratory, described and exhibited a carbon tube furnace for testing the softening points and compressive strengths of refractories.

The paper describes a carbon tube furnace designed for the testing of refractory materials under definite load.

The specimens are cut from the brick and ground up into the form of short cylinders. Pressure is applied by means of springs suitably connected to carbon rods which carry the specimen under test.

Two simple forms of electrode construction are described. In one of them the current is carried by two copper tubes bent into a zig-zag form and cast into two blocks of white bearing metal. The faces of the blocks are cast to the form of the carbon tube to which they are clamped. The copper tubes also serve for water cooling.

The temperature of the specimen is directly observed by means of a polarizing type of optical pyrometer. For this purpose a slot $\frac{1}{4}$ in. wide extends the entire length of the tube. A slot was made in preference to a round hole, since the latter would have produced a discontinuity in the resistance of the tube.

In the discussion Dr. W. Rosenhain remarked that the results obtained depended upon the surfaces between the little columns being absolutely true. In the case of a material which softened with temperature the results would be affected by the intensity of the pressure.

Mr. H. M. Ridge said he was glad to know of an apparatus that could be subjected to over 1500° C. and at the same time give accurate tests of firebrick materials. He hoped that if comparative tests had been made on the standard bricks they would be published. The recent regulation fixing a maximum price for firebricks militated against the good brick, but enabled the maker of inferior bricks to raise his prices. The use of an apparatus like that described would enable a sliding scale to be fixed on a basis of actual tests.

Dr. H. Borns asked how long a test took.

Dr. H. C. Greenwood asked whether tests had been made on the effect of temperature on tensile strength.

Dr. R. Lessing thought the test pieces used in the furnace rather too small, especially for large-grained material.

Mr. E. Griffiths, in reply, said there was no difficulty in applying the pressure normally. Usually three specimens were taken from a brick and the results only accepted when concordant. A small test-piece ensured uniform distribution of temperature. A test usually took $2\frac{1}{2}$ hours at a 10° C. increase of temperature per minute. Comparative tests could not be published at present, but he might say that a magnesite brick broke down at 1500° C. when heated uniformly, under a pressure of about 30 lb. This was about the normal.

Electrochemistry

Electrochemical Analogies of Photochemistry.—At the Cleveland meeting of the American Physical Society, Oct. 27 and 28, 1916, WILLIAM ROY MOTT of the National Carbon Company's Research Laboratory, Cleveland, Ohio, read a paper on "Electrochemical Analogies of Photochemistry." An abstract was published in the *Physical Review* for January, 1917. The author has made experiments on dye fading and other photochemical reactions and has come to the conclusion that the general theory of the electrochemistry of photochemistry can be revised to a more concrete form than expressed by the theory of Grothuss. In the revised theory the two electrochemical factors of current and voltage are respectively related to amount of light and wave-length of light.

He first discusses the analogy of current and amount of light, citing Faraday's law and the photochemical law, that the amount of chemical action is nearly proportional to the energy of the light absorbed in the photochemical reaction chamber. The limitations of these laws, viz.: the necessity for a certain minimum voltage in Faraday's law and the wave length limits in the photochemical law are discussed.

The great importance of absorbing media in photochemistry leaves no apparent relation to electrochemical equivalents as in electrochemistry in going from

one material to a different material. The departures from apparent proportionality can be explained, however, in a manner similar to the apparent departures of electrochemical reaction from Faraday's law in a given electrolyte.

In developing the analogy of voltage and wave-length the author considers the wave length as an intensity factor of light corresponding to voltage as an intensity factor of electricity, and cites examples showing how the shorter wave length light has a greater chemical effect. The following table illustrates the generalization:

Material	Formula	Voltage for decomposition	
Calcium fluoride...	CaF_2	4.7	Most transparent to far ultraviolet.
Hydrofluoric acid...	HF	2.2	Not decomposed by far ultraviolet.
Hydrochloric acid...	HCl	1.7	Slightly decomposed by far ultraviolet.
Hydrobromic acid...	HBr	1.2	Easily decomposed by ultraviolet.
Hydroiodic acid...	HI	0.6	Easily decomposed by blue light.

A curve could probably be constructed between wave length of light required and decomposition voltage required. It is interesting to note that the extremely short waves are readily absorbed by everything except the *non-reactive* noble gases.

This theory can be further expanded to show a relationship between heat of formation (on electrochemical equivalents and refractive index and point of probable absorption of light as the curve is carried into ultraviolet region. Also, the theory has fascinating possibilities in predicting the character and probability of light production by chemical change.

Glass

Union of Glass by Heat Treatment.—A paper on "The Union of Glass in Optical Contact by Heat Treatment" was presented at the Faraday Society meeting in London, Dec. 18, 1916, by R. G. PARKER and A. J. DALLADAY. The paper gives the results of some interesting experiments on joining glass.

Two pieces of glass in optical contact can be made to join completely, and become one piece, by carefully controlled heating. The temperature employed is very far below the melting point, being 80 – 90° C. below the annealing point; the glass components therefore unite without softening and without deformation of unsupported optically worked surfaces. Slight pressure is usually applied. The components, after treatment, are not separable by any of the means which suffice to separate pieces in optical contact, viz., by liquids (capillarity), by sudden small temperature changes, or by mechanical force. When subjected to the last of these, or cut with a diamond, a composite block breaks as would one piece. The accuracy of the parts is unaltered by the heating, and it is not difficult to prepare by this method cells having windows parallel to one second, with optically worked surfaces in the interior. Within limits, different kinds of glass can be joined; their expansion coefficients must not differ greatly, nor must the annealing points differ by more than 50° C.; they must also be kinds which will fuse together in a blow-pipe flame. Only when the components are all of one kind of glass can the composite article be freed from strain by annealing. Fused silica plates unite at 1030° C.

Dr. W. Rosenhain regarded the authors' results as a remarkable achievement. He thought that various methods of polishing might make a difference in the behavior of the glass. He discussed the behavior of moisture or hydrated films as affecting the union.

Might not chemical cleaning give better results than mechanical?

Professor Alfred W. Porter thought the fact that the outside surface film of the glass was in a totally different condition from that of the inside was responsible for the possibility of the process. The outside film would be practically in a flowing state.

Mr. Dalladay, in replying said chemical cleaning might be useful, but it had not when tried given good results. Such trouble as occurred was caused by little pieces of cellulose left from the material used for wiping the surface.

Transportation

Transport of Corrosive Liquids by Water.—The transportation of acids and other corrosive chemicals has always been a difficult problem. In the *Journal of the Society of Chemical Industry* for December 30, 1916, H. N. MORRIS describes a method of transportation in a tank boat, following out the ideas of the oil tankers developed 10 years ago by the Standard Oil Co. He reviews the common methods of transporting acids at sea and shows that they are in general costly and dangerous to the ship, although cases are known where no accidents have occurred for many years. At the best the methods are, however, very costly. The author describes a proposed design for what he terms a "sub-aqueous acid tank," consisting of two shells or tanks, one within the other. The inner tank, which carries the corrosive liquid, may be suitably lined with lead, aluminum, bitumen, or materials depending on the liquids to be transported. By towing this tank, a safe and economical means of transport is provided. A light on the tank is required to safeguard against loss.

A tank of 250 tons of ordinary conc. H_2SO_4 is described, which could be used equally well for oleum, which would solidify, but could be easily melted by passing steam into the outer case until the contents of the inner tank were liquid. In this case it would be better not to line with lead, but to use stronger iron.

It could also be used for hydrochloric acid if the lead lining were covered with a uniform coating of bitumen. It could be used for the conveyance of nitric acid if lined with aluminium. As the inner tank is divided into three compartments three different acids or corrosive liquids could be transported at once.

In many cases a return cargo of oils or other liquids could be obtained. The tank is not suitable for very small quantities, but for short distances, 100-ton or even 50-ton tanks might be used economically, and there are not many countries where it would not be possible to dispose of 250 tons of either sulphuric acid or mixed consignments. The tank can be used for many acids and other chemicals: sulphuric acid, oleum, hydrochloric acid and nitric acid, carbon bisulphide, alcohol, benzol, toluol, or naphtha, which, although they cannot all be classed as corrosive, are more or less dangerous for a steamship company to carry.

New Swedish Nitric Acid Company.—A new company with large capital has been formed for the manufacture of nitric acid and other chemical products in Sweden, according to the *Chemical Trade Journal*. It has entered upon a contract with the Royal Waterfalls Board for a supply of electric energy, and the works will be erected on the area reserved for industrial installations at Trollhattan. The annual capacity will be some 7000 tons concentrated nitric acid, with nitrates as an auxiliary product. The new company will use the Birkeland-Eyde method, for which rights have been secured for Sweden. The work is being pushed ahead with all speed to be ready this year.

Recent Metallurgical and Chemical Patents

Copper

Hydrometallurgy of Copper.—A patent was granted to EDWARD RAY WEIDLEIN, of Thompson, Nev., for the extraction of copper from its ores by means of sulphuric acid and the precipitation of the copper from the sulphuric acid by means of sulphur dioxide, according to the equation, $\text{CuSO}_4 + \text{SO}_2 + 2\text{H}_2\text{O} = \text{Cu} + 2\text{H}_2\text{SO}_4$.

FIG. 1.—PROCESS FOR EXTRACTING COPPER

Fig. 1 represents the flow sheet of the process. In preferred practice the ore is leached with a 3.6 per cent sulphuric acid solution, the solution is then neutralized and the copper sulphate solution containing about 1.5 per cent copper is treated with an approximately equal amount of sulphur dioxide. The solution is then heated in the precipitation tanks to 150 deg. C. at a pressure of about 100 lb. per square inch. Under these conditions the copper will be precipitated. It is removed by filtration, and the solution is re-used for leaching. The process, it is claimed, may be used on ores, mattes and other copper bearing materials. (1,201,899, Oct. 17, 1916.)

Method of Connecting Electrodes in Electrolytic Refining.—ROBERT L. WHITEHEAD of Perth Amboy, N. J., has been granted patents on a method of arranging the electrode connections in a series of electrolytic vats, and on a method of making the individual contact. The method was developed in connection with the electrolytic refining of copper. The patents have been assigned to the American Smelting & Refining Company of Maurer, N. J. The original application was filed in February, 1913, containing claims to both the form of contact and the manner of arranging the connections. The application was subsequently divided and these two claims presented in separate applications. The method of arranging the connections is to connect the cathodes of one vat directly to the anodes of the adjacent vat, instead of as heretofore having two sets of contacts along the common bar supporting the cathodes of the first vat and the anodes of the second vat.

By connecting the cathodes of one vat directly to the anodes of the second vat the common busbar is dispensed with and the number of contacts is reduced to one-half. The connection, which is the subject of a second patent, is made by cutting a V-shaped groove in one electrode and making a projection on the other electrode to fit into this groove (1,206,963-65, Dec. 5, 1916).

Alloys

Nickel-Chrome Alloy.—An alloy of high melting point and high resistance to the dissolving action of acids and alkalis has been patented by THEODORE B. BRIX of Newark, N. J. It consists of not less than about 55 per cent of one of the metals of the nickel group, from 15 to 35 per cent of chromium, chromium and tungsten or chromium and titanium and not over 10 per cent of silicon. Usually nickel, chromium and silicon are the constituents used, but for certain purposes, cobalt may in part replace the nickel, or combinations as mentioned may replace the straight chromium. In varying the metals, high resistance to temperature, insolubility in acids and alkalis, malleability or ductility may be attained. Other metals such as copper, boron, aluminium and manganese may be used in small amounts. The preferred alloy, embodying practically all the desired properties, is given as from 60 to 75 per cent by weight of nickel, 15 to 20 per cent of chromium, 5 per cent copper, 4 per cent silicon, 1 to 4 per cent tungsten, 2 per cent aluminium, 3 per cent manganese-titanium (2.3 manganese) and 1 per cent boron. A method for the production of said alloy is described. (1,203,180, Oct. 31, 1916).

Sintering

Method and Apparatus for Sintering Metals.—An apparatus for the sintering of metallic powders, such as tungsten, has been patented by RAYMOND B. WALLING of Newark, N. J. Fig. 2 represents the apparatus employed. The apparatus proper is enclosed in a copper treating bottle, cylindrical in shape. The bottle is provided with a jacket 2. Between the jacket and the

FIG. 2—SINTERING APPARATUS

bottle is a space for the circulation of a cooling medium, such as water, which enters at pipe 4 being discharged through 3. In its lowered position the bottle rests on plate 5 and is rendered gas-tight by gasket 6. During the process of operation, hydrogen gas or some other inert gas is circulated through pipes 7 and 8; 9 is the upper electrode and is made of the material which is to be sintered (in this instance tungsten), the electrical contact being made with copper clamps 10 and 11. Cooling arrangements are provided for the electrode holders; 18 is the lower electrode, and is firmly set into the copper casting, which floats in mercury bath 20; 21 is a screw which regulates the height of the mercury and also the downward motion of the electrode 18. Cooling devices are also described for this electrode. 35 represents the tungsten rod which is to be sintered by means of heat generated by the resistance of the passage of an electric current through the rod. The main features of this apparatus are the use of the electrical current and the floating mercury contact for the lower electrode. It is claimed that by using this method there is no waste whatever, as the rod is perfectly sintered throughout its entire length (1,194,906, Aug. 15, 1916).

Apparatus for Roasting and Sintering Ores.—A patent granted to JAMES GAYLEY of New York, N. Y., involves improvements made on the Dwight-Lloyd type of sintering machines. The main feature of the improvements consists in making the joints between the moving pallets and the wind box automatically tight, thus preventing the impairment of the airtight union between the two. Fig. 3 represents the longitudinal

FIG. 3—ROASTING APPARATUS

section of a part of the machine and Fig. 4 is a vertical cross-section of the same. A train of pallets A moves continuously over the top of the wind box B. The means of locomotion of these pallets is similar as in the Dwight-Lloyd machine. The whole length of the wind box top is fitted on either side with a rectangular wearing bar F, and at each end it is filled with a dead plate

FIG. 4—ROASTING APPARATUS

C', over which the whole width of the pallet slides to prevent the leakage of air at these points. The wearing bars constitute the fixed member of the sliding joint which is maintained between the pallets and the wind box. Bars or plates fit in grooves *K* in the under surface of sides *H*. These bars or plates are termed curtains and are designated as *L*. In their simplest form these curtains consist of rectangular plates or bars, having the same length as the pallets. These plates or bars fit into the recesses in the pallet with only sufficient clearance to permit free movement of the pallets under their own weight. *M* are rods or pins which prevent the endwise movement of the curtains in the pallets. These improvements, it is claimed, give the desired automatic airtight joint (1,197,199, Sept. 5, 1916).

The Utilization of Waste-Products and of Low-Grade Fuels for Power-Generation

By John B. C. Kershaw, F.I.C.

TOWNS' REFUSE

The rising cost of all classes of coal and slack due to causes, some permanent and some we may hope only temporary in character, but which it is unnecessary to analyze here, renders the discussion of the utilization of waste materials and low-grade fuels for power purposes of particular value at the present moment. The power engineer has been badly hit by the increase in the cost of fuel, and since it is highly probable that a large share of this increase will prove to be permanent, it is necessary that he should take a wide survey of all combustible materials, and impress into his service any that promise to yield a fair return for their cost of collection and cartage, as fuel for his plant.

Foremost among the waste materials that may be utilized as substitutes for ordinary fuel, is that of towns' refuse, since not only is its quantity large, but its destruction by burning is imperative in all large towns and crowded centers of population. Further, the heat produced by its combustion is most easily utilized by means of steam boilers and electrical generators, and the slag produced by its combustion may also prove a valuable source of revenue.

In this article the writer proposes to discuss:

1. The published data relating to the calorific value of this refuse for steam raising purposes.
2. Recent improvements of the destructor process.
3. The practical value of refuse destructors from the standpoint of the power engineer.

I. THE CALORIFIC VALUE OF TOWNS' REFUSE

It must be admitted that many of the published figures relating to the calorific value of towns' refuse are unreliable and misleading and that some of the earlier estimates of the number of kilowatts that might be produced from a ton of refuse were much too high, and have only been approached in specially situated districts where the calorific value of the refuse is unusually good.

Towns' refuse is a product that varies greatly in composition and value, not only in different towns, but also in the different districts of the same town, and at different periods of the year. The only figures that are reliable as to its calorific value therefore, are those based upon twelve months' operation of the destructor plant, since the summer value of the refuse is generally lower than the winter.

In colliery districts where the miners' families obtain their coal for nothing, or at a nominal price, and the general public pay only about one-half of the price charged to the consumers in large towns, the fuel value

of the refuse will also be twice as high, owing to the presence of much unburned carbon in the cinders.

In towns and cities far from coal-mining districts on the other hand, the refuse will be found to consist largely of kitchen and garden garbage, which, if wet, has little value for steam-raising purposes.

Bearing these facts in mind, one can now proceed to examine and analyze the figures obtained in tests of the more recently erected destructor plants, with a view to ascertaining the real fuel value of the refuse collected from a town of average size. The figures presented are mostly those obtained during test runs of the plant when taken over from the engineering firm which designed and erected it, and a standing deduction of 33.3 per cent will be made from these figures, in order to bring them into line with the results that may be expected from twelve months' practical operation of the plant. This percentage deduction has been arrived at by study of the comparative data published in the early years of destructor development for short test runs, and for one year's operation of combined destructor and electric generating plant.

THE HORSFALL DESTRUCTOR

"The New Destructor Company," who now control the Horsfall system of refuse destruction give, in a recent publication, a tabular statement showing the gradual improvement in the efficiency of their destructors during the period 1900-1910. The results are based on tests of not less than twenty-four hours' duration, and the water evaporated per pound of refuse shows an increase from 1.21 lb. for the destructor erected at the Pembroke Electricity Works, Dublin, to 1.57 lb. for the Poplar Electricity Works, in 1910. The details of this latest available test for the Horsfall type of destructor are as follows:

Place—Poplar.

Date of test—Feb.-March, 1910.

Tons of refuse burned per twenty-four hours—153 tons.

Evaporation per pound of refuse at 212 Fahr.—1.57 lb.

The adoption of closed tubes with hopper bottoms for storing the refuse at the destructor plant until charged into the furnaces, and of a mechanical clinkering grate in the form of a tipping truck, are the latest improvements of the Horsfall Destructor.

THE HEENAN AND FROUDE DESTRUCTOR

The following results of recent tests with the Heenan and Froude type of refuse destructor are of special interest, since they emphasize the great variation in the thermal value of the refuse in different parts of the country, and illustrate the remarks made on this point in the introduction to this article.

Town	Date of Test	Period of Test	Lbs. of Water Evaporated per Lb. of Refuse
Aberdare (S. Wales)	March 24, 1915	10 hours	3.53
Pontypridd (S. Wales)	Feb. 10, 1910	8 hours	2.69
Coventry	April, 1911	48 hours	2.00
Rotherham	Jan. 27, 1910	18 hours	1.80
Clydebank	May 2, 1907	8½ hours	1.73
West Bromwich		8½ hours	1.15
Swinton	Sept. 24, 1912	11 hours	1.32
Cheltenham	June 26, 1908	17½ hours	1.24
Rotterdam	Feb. and May, 1913	6 days	1.10
Rotterdam	Feb. and May, 1913	10 days	.88

N.B.—These are actual evaporations, and are not expressed on the standard basis "from and at 212 deg. F."

The adoption of water-sealed charging devices, and of improved methods of withdrawing and quenching the clinker, are some of the latest improvements in the Heenan and Froude type of destructor.

FOREIGN TYPES OF DESTRUCTOR

The first destructor erected in Germany was that at Hamburg in 1896, a result of the cholera epidemic in the previous year. This was of the Horsfall type, and some trouble due to the use of steam jets was experienced before it worked satisfactorily. Brussels followed the example of Hamburg in 1903, and Zurich in 1904, by erecting similar destructor plants. These were also of the Horsfall type. The first German-designed destructors were those erected at Wiesbaden by Dörr, and at Kiel by Herbertz, in 1905-1906. These designers made use of the principle of using hollow chambers in the walls of the destructor cell for the purpose of heating the incoming air, which was forced by fans into the combustion chamber under a pressure of 400 mm. (16 in.) water.

As might be expected from the methods of domestic heating in use in Germany (by closed stoves using chiefly briquette-fuel) the refuse collected in German towns and cities is less rich in combustible material than English refuse. At *Puchheim*, the evaporative efficiency is 0.891 lb. of water per pound of refuse, (equivalent to 1.01 lb. from and at 212 deg. Fahr.) while at *Fürth* (Humboldt system) the actual evaporative efficiency is 0.98 lb. water per pound refuse, equivalent to 0.97 lb. from and at 212 deg. Fahr. The general results obtained at these two installations show that German refuse has an average heat value of only 2160 B.t.u. per pound, and that about one-half of this heat value can be utilized for steam-raising purposes.

The English figures, consequently, show much higher evaporative efficiencies, the average for the Heenan and Froude type of destructor being over 1.87 lb. water per pound of refuse and that for the Horsfall destructor being 1.38 lb. Taking 33.3 per cent off these figures we have 1.25 and 0.94 lb., respectively. It is unlikely, however, that in view of the increased price of fuel in recent years and the urgent necessity for the practice of economy on the part of all sections of the population, that English house refuse will in future contain so much cinder and unburned carbon as in the past, and it will be wiser, therefore, to assume that the average calorific value of towns' refuse, when calculated upon twelve months' working of the destructor, is about 2160 B.T.U. per lb., and that only 1 lb. of water can be evaporated per lb. of refuse burnt, for steam-raising purposes. The practical application of these figures will be discussed in the third portion of this article, when discussing the generation of electricity from house refuse.

II. RECENT IMPROVEMENTS AND THE CONTROL OF THE DESTRUCTOR PROCESS

The difficulties met with in the destruction of house refuse by burning are chiefly those arising from the physical character of the materials to be consumed, and the large amount of clinker produced as a result of the combustion of the refuse. Kitchen garbage and similar refuse is generally wet, and will not burn at all until dried, while the rags, waste paper and cinders, that form the other chief combustible elements of the refuse, are so distributed and buried among the mass of incombustible material that it is very difficult to get an adequate air supply at the points where it is most required. According to Broadbent, the average composition of London refuse is as follows: Ash, 47 per cent; breeze and cinder, 25.5 per cent; paper, straw and vegetable refuse, 13 per cent; dust and dirt, 9.75 per cent, while the remaining 4.75 per cent is made up of bones and offal, rags, bottles, crockery, broken glass and tin cans. The combustible material, therefore, does not amount to more than one-third of the whole, and

the difficulties of burning it are much greater than those encountered in burning the poorest qualities of slack or coke breeze containing 30 per cent to 35 per cent of ash.

When the combustion has been successfully effected the fused clinker that remains behind is over one-third the weight of the original charge of refuse, and special forms of grate and special appliances are necessary in order to deal with this large amount of molten matter and to avoid heat losses by its withdrawal from the furnace.

The difficulties of attaining complete combustion have been overcome by the use of fans for supplying preheated air under considerable pressure, perforated iron plates being employed for the furnace sides and bottoms in many of the newer types of destructor in order to distribute this air through the whole mass of material to be burned. The air is preheated either by passing through the hollow well spaces between the different cells of the destructor or by special air heaters placed in the hottest part of the combustion chamber of the furnace. It is now recognized by designers of destructor cells that a preheated air supply is a *sine qua non* of good destructor working, for a difference of 300 deg. C. in the temperature of the incoming air makes a difference of 350 deg. to 400 deg. C. in the actual temperature attained in the furnace. The advantages of a preheated air supply are not confined to this increase of thermal efficiency, for a quicker ignition of the refuse and an accelerated combustion accompany the use of hot air, and the capacity of the destructor per day of twenty-four hours is therefore greatly increased.

As regards the improved methods of dealing with the clinker, it has been found by actual measurements that the heat retained in the fused mass only amounts to from 3 per cent to 4 per cent of that generated, and attempts to utilize this heat for raising the temperature of the incoming air or for other purposes have not proved so successful as was hoped. The use of water-cooled mold-shaped grates which facilitate the removal of the clinker in one mass and of a bar bent in a spiral form around which the clinker melts are the latest devices for dealing with the clinker problem, since by means of a ring-shaped handle to the clinker bar and a winch a mass of fused clinker weighing several hundredweights can be removed from the furnace with ease by one man.

As regards charging the refuse into the destructor, the double-bell system has been improved upon, a whole charge now being dropped into a water-sealed pocket in one operation before the lower bell is raised and the charge is passed on into the furnace.

The latest development of destructor design, however, is the adoption of the blast furnace as the model of what a refuse destructor should be, the Dörr destructor erected at Wiesbaden being the first of this type. Improved forms of the shaft type of destructor have been erected at Barmen and Hamburg, and as these represent a distinct departure from the ordinary type of destructor design, and can be operated with reduced costs, a few details of their construction and method of working are appended. The original Hamburg furnace was constructed in the form of an octagonal shaft, the hearth of which was rectangular in form and water-jacketed for cooling purposes to prevent the clinker adhering to the walls. A perforated iron gating was used for distribution of the air supply, and a fan supplied air under pressure to the air chamber below the grating. This furnace gave a mean temperature of 1050 deg. C. and burnt successfully 31 tons of refuse per day.

An improved form of the Hamburg shaft furnace

was erected later at Barmen. In this case a preliminary grate was provided in front of the grating of the shaft furnace, and on to this the clinker cake was drawn and remained twenty to forty minutes, in order that it might give up some of its heat to the incoming air. As already stated, the heat losses with the clinker are small and the temperature of the incoming air cannot be raised to any considerable extent by contact with it.

The latest types of the shaft destructor furnace have, therefore, adopted special air heaters placed in the hottest part of the system for preheating the air supply, and only use the clinker heat for the preliminary step in the preheating process.

Kohlmann,* in a valuable paper upon the "Evolution of the Refuse Destructor," read before the Canadian Section of the Society of Chemical Industry in 1913, has given the following figures for the capacity of the various types of destructor, and if these can be accepted as reliable the superiority of the shaft type of furnace with preliminary air heating is amply demonstrated. The fact that with this type of furnace the labor costs for charging and removing the clinker are also reduced to a minimum would indicate that in time we may expect to find all dust destructors approximating to this type of design.

III. THE PRACTICAL VALUE OF REFUSE DESTRUCTORS FROM THE POWER ENGINEER'S STANDPOINT

The figures given in the first section of this article prove that house refuse has an average heat value of one-seventh that of ordinary coal, and that about 1 lb. of steam can be produced per pound of refuse burnt. Has such a poor fuel any value at all from the power engineer's standpoint? If this question were decided solely upon the value and merits of this refuse as a fuel, the answer to the question would be in the negative, for the interest upon the capital outlay on the destructor plant and the costs of working it would amount to more than the value of the steam produced. But, as pointed out in the introduction to this article, the question of refuse destruction by burning is fundamentally a sanitary one. All large towns and cities ought to be provided with destructors with sufficient capacity to cremate the whole of their refuse, and the question of utilizing the surplus heat to the best advantage is really an economic one, bound up with the successful operation of these plants.

In the early days of destructor development it was customary to erect and work these plants as adjuncts of the electricity supply stations, and it was claimed that from 40 to 60 units of electricity could be obtained in these combined plants per ton of refuse burnt. The

L. S. D. value of the latter as fuel was calculated therefore to be 3s. 4d. (\$.80) per ton.

The electrical engineers in charge of large power-generating stations, however, were not in favor of the system, since a certain amount of nuisance and dust detrimental to the efficient working of the machinery arose from the carting and tipping of the refuse, and only a few of these combined plants have been erected in recent years.

The modern plan is to erect the destructor on the site most suitable for the collection of the refuse, to operate it as an independent works, and to sell the steam produced by the surplus heat to the nearest factory or works at an agreed rate per 1000 lb. In some cases this sale is to an electricity supply station, but this is not an essential feature of the plan, and any large works that requires steam for heating or power purposes might cover a portion of its requirements from a destructor plant if one were near at hand. As examples of this system of working, the destructor plants at Huddersfield, England, and at Rotterdam, Holland, may be referred to.

The Huddersfield destructor was erected in 1910 by Manlove & Alliot of Nottingham, and consists of eight furnaces or cells, arranged in two units of four cells each, each unit being complete with its own combustion chamber and water-tube boiler. The cells are of the "back-feed" type, and are arranged on the continuous system. Each cell has a grate area of 25 sq. ft. and is provided with a drying hearth at the rear, where the green refuse is subjected to a preliminary drying. Forced draught is provided by two electrically driven fans, and the air is preheated before its entrance into the combustion chamber. The surplus steam not required for the operation of the destructor plant is carried by well-insulated steam mains over a roadway to the electricity works, and is sold to this undertaking at a net cost of 7d. (14 cents) per 1000 lb. The annual revenue received by the destructor plant from this source in the four years 1911-1914 has been as follows: 1911, \$7,525; 1912, \$8,795; 1913, \$8,950, and 1914, \$8,505.

The Rotterdam plant was erected in 1911, and was first put into operation in 1912. The destructors are of the well-known Heenan & Froude type, and are provided with all the improvements brought out by this firm in recent years. The plant consists of five independent units, each consisting of two sets of four cells, grouped on either side of a central combustion chamber. The grates of four adjoining cells are separated from one another by low cast-iron transverse dead-plates of hollow construction, so that the four grates practically form one continuous furnace chamber.

Each unit is fitted with a "regenerator" consisting of a group of vertical boiler tubes expanded at the top and the bottom into horizontal tube-plates. The hot gases from the boilers pass through the tubes and down into dust pits, while the draught air passes over the outside of the tubes.

The most striking feature of the installation, however, is the system of collecting the house and street refuse of the city and of bringing it to the destructor furnaces with a minimum of nuisance and cost. The city is divided into five districts, in each of which there is a small dock for accommodating barges. To these docks the refuse is brought in tip-carts, which tip the refuse direct into skips, a number of which fit neatly into a barge. The refuse never leaves these skips until it goes into the furnaces. Each barge holds about 2 dozen skips and each skip contains about 1600 kg. (31.5 cwt.) of refuse. The skips have bottom doors, which can be tripped when the device is lowered into its seat-

*Journal Soc. Chem. Industry, April 30, 1914.

ing over the furnace; also they are made larger at the bottom than at the top, so that the rubbish will fall out quite readily.

It is chiefly in this respect that the older systems of destructor working were faulty and capable of improvement, and although the possession of canals that ramify all through the city simplifies the collection and transport of the refuse in Rotterdam, there is no doubt that many of the good points of the Rotterdam system might be copied with considerable success in other towns and cities.

The official trials of the plant, made during separate runs in February and May, 1913, showed that 1214 tons and 1228 tons of refuse had been cremated, with an evaporation of 1.106 lb. and 0.889 lb. of water per pound of refuse burnt respectively, an average of 144 tons per day, and 0.99 lb. steam for the whole seventeen days' period of trial. The steam raised is used partly in the plant where the clinker is crushed and graded to three sizes, and all iron is removed by magnetic separators, while the surplus is sold to the municipal electricity supply department at the fixed rate and is used for driving a 1250-kw. turbo-generator.

The city electricity department provided half the capital required for the electrical portion of the plant and for the building in which it is housed, pays the whole of the running charges of the same, and 0.10 penny (0.20 cent) per unit for the steam. Further details of this interesting plant will be found in the descriptive article from which these facts are taken, which appeared last year in the publication referred to below.*

The one disadvantage of the Rotterdam system of working appears to be that there is no opportunity for sorting the refuse and removing from it the paper, old metals and broken glass, all of which have a marketable value, especially at the present time.

As an indication of the annual revenue that may be derived from this source by a destructor plant, the following figures from the 1914 report of the chief sanitary inspector of Paisley in Scotland, are of interest: 17,576 tons of refuse, or an average of 50 tons per working day, was collected and dealt with in 1913, and 3177 tons of clinker and 243 tons of mortar were sold in that year.

The revenue of the destructor plant from the sale of the residual products was as follows:

Clinker	\$1,120
Mortar	240
Old tins and scrap metal	546
Waste paper	76
Old bottles	20
Total	\$2,006

In view of these figures, and of the fact that the relations between the sanitary and electrical departments at Huddersfield and Rotterdam are most harmonious, it would seem probable that a considerable increase will occur, during or after the war, in the number of destructor plants for towns' refuse equipped with the most efficient types of furnace, and that these plants will all derive considerable revenue from the sale of their surplus steam to the neighboring works and from the disposal of their clinker and other by-products to those who can make good use of these commodities in their operations.

If the experience of Huddersfield and of Paisley is a safe guide, an aggregate revenue of between \$11,800 and \$14,400 can be obtained in all large cities from these two sources alone, and a considerable portion of the cost of destroying the refuse can thus be met.

Personal

Prof. Wilder D. Bancroft was in New York on Thursday, Feb. 8 and delivered a lecture in the evening at Columbia University on "Contact Catalysis" under the auspices of Gamma chapter, Phi Lambda Upsilon, and as a part of the extension teaching course.

Dr. V. A. Coulter has been appointed assistant professor of chemistry at the University of North Carolina.

Mr. Samuel H. Dolbear, consulting mining engineer, has removed his offices to 1411-12-15 Merchants' National Bank Building, San Francisco.

Mr. Gustav Drobegg has resigned his position with the Beckers Aniline & Chemical Co., Inc., to accept the superintendency of plant D of the Butterworth-Judson Corporation, at Newark, N. J.

General Geo. W. Goethals has opened consulting offices in the Wall Street Exchange Building, 43 Exchange Place, New York. A number of experienced specialists are associated with him, and a general consulting practice in civil, electrical, mechanical and hydraulic engineering will be engaged in.

Mr. Walter Kidde, engineer-constructor, of 140 Cedar Street, New York, has incorporated his organization under the title of Walter Kidde & Co., Inc. The business was established in 1900 and has grown steadily. One of their most recent commissions is the plant of the American Hard Rubber Co., at Akron, Ohio. Mr. Kidde's chief associates, who have been his partners on the "Carnegie Plan," will now become directors and stockholders of the new corporation, the officers of which are: Walter Kidde, president; B. G. Worth, vice-president; I. R. Lewis, secretary and treasurer. These are all members of the board of directors, which also includes Henry Lang, who is vice-president of the Ingersoll-Rand Company, and E. S. Boyer, who is associated with the American Hard Rubber Company. Mr. Kidde's other principal associates, who comprise the engineering board of the corporation, are: A. B. Miller, Walter S. Wainright, M. I. Buttfield and E. Schwarz. The chief draftsman is Thorlief Fliflet.

Mr. A. R. Levin has become associated with the Supplee-Biddle Hardware Company as manager of the New York office, 30 Church Street.

Mr. O. C. Martin, who has been with the Nichols Copper Co., Laurel Hill, Long Island, for several years, has been made works manager of the company.

Mr. John G. Mason has become associated with Ralph L. Fuller & Co., Inc., 20 Rector Street, New York, as manager of their chemical and drug division.

Mr. J. Henry Rickard has recently returned to England from the United States.

Dr. A. H. Ney announces that he is in no way now connected with any consulting business or laboratory, firm of chemical engineers or manufacturers of chemical apparatus, and that any such connections which have existed, have been discontinued. His entire time is taken up with work in connection with the development of the chemical products and dye manufacturing plant of the Sherwin-Williams Company, of which he is the head, and he is not willing to consider propositions for his services in any form whatsoever, matters pertaining to national defense or economical development of the national resources alone excepted.

Mr. Paul Noble, recently with the Bayer Company, has become sales manager of the American Aniline Products, Inc., whose office has been removed from

15 East 12th Street, to 120 Hudson Street, New York City.

Professor E. F. Northrup, research physicist of Princeton University, has been awarded the Elliott Cresson medal by the Franklin Institute "in recognition of his electrical inventions and high temperature investigations."

Mr. Robert Carl Schroth, Jr., president of the Laboratory Supply Co., of Columbus, Ohio, and Mr. C. D. Fraunfelder, president of the Ohio Pottery Co., of Zanesville, Ohio, were in New York and attended the meeting on "Chemical and Electrical Porcelain" held at the Chemists' Club on Friday, Feb. 9. Both report great activity in their line.

Mr. A. M. Webb, assistant manager of the Chemical Construction Company, was married on January 11, to Miss Jean Harper, at Charlotte.

Professor W. M. Weigel has resigned as professor of mining at Pennsylvania State College, to become superintendent of the concentrating mills of the International Molybdenum of Renfrew, Ont.

Book Reviews

Pipe and the Public Welfare. By R. C. McWane. 165 pages, illustrated. Price, \$1.00. New York: The Stirling Press.

This little volume was written for the purpose of showing the advisability of using cast-iron pipe for conduits and contains much that is of historical and practical interest. The author first discusses the history of the use of pipe in an interesting manner, beginning with the crude clay pipe of early Babylonian days, 4000 B. C. The history covers the introduction and development of iron and wood pipe, accounts of the water-supply systems of the large cities, and the use of iron pipe for gas mains. He then gives a review of materials and methods used in making metal pipe, which is followed by a long discussion on metal pipe deterioration, the latter being mostly in the nature of practical evidence of the rust-resisting qualities of cast iron. The last chapter is devoted to a discussion of the use of wood pipe. Concrete and clay pipe are purposely omitted, as these are not used to any extent in pressure conduits. Many interesting illustrations are included in the book.

Selling Your Services. By the Sales Service Company. Price, \$1. New York: The Sales Service Company, 627 Madison Avenue.

It is a little difficult at first for a technical man to think of his services or ability as a distinct commodity which can be marketed according to accepted principles of salesmanship. Yet here is a delightful little book which says that this is true and shows how to apply these principles to the obtaining of a position by a technical man. It is written in a convincing manner with many typical letters, and entirely from the salesman's viewpoint on accepted business principles.

A Text Book of Inorganic Chemistry.—Vol. VIII: The Halogens. By G. Martin and E. A. Dancaster. Crown octavo (15 x 22 cm.). 337 pages, 30 illustrations. Price, \$3. London: Charles Griffin & Company, Limited. Philadelphia: J. B. Lippincott Company.

Although numbered VIII in the series, it is the second to be issued. The other volumes are in preparation or in press. Both the editor of the series, Dr. J. Newton Friend, and the immediate authors of this volume emphasize the idea that the work is not intended to be exhaustive, that technical details are briefly touched

upon, and that most attention is given to the chemical and physical properties of the elements concerned and their compounds. The consequence of applying these principles is that the work is neither one thing nor another, neither an inspiring text-book nor a complete hand-book, but it has a certain value as a reference book if completeness is not expected, and from this viewpoint the present volume on halogens is not without merit.

The Mineral Industry: 1915. Edited by G. A. Roush. Octavo (15 x 23 cm.), XX + 941 pages; price \$10. New York: McGraw-Hill Book Company, Inc.

Volume XXIV looks as important and portly as its noted predecessors, while its pages, on inspection, bear out the statement that in quality of content it is the equal of its ancestors. There is not much need to praise it further than this, except to remark that the gathering of foreign data and statistics for 1915 was necessarily a work of the greatest difficulty, and everyone consulting the work will be impressed with the success attending the editor's efforts under such unusual handicaps.

Many of the regular contributors are represented (they are too many to catalog in a review), but several new and familiar ones have been added to the galaxy, such as J. W. Beckman on "Borax and Potassium Salts," R. M. Keeney on "Radium, Uranium and Vanadium," E. H. Leslie on "Gold and Silver in Mexico," E. S. Moore on "Gold and Silver in Australia and India," Balfour Scott on "Tin," L. O. Snyder on "Gypsum in Oklahoma," M. W. Von Bernewitz on "Gold and Silver in the United States," and on "Flotation."

Report on the Fertilizer Industry. By the Federal Trade Commission. U. S. Government Printing Office, August, 1916.

This 290-page report, prepared mostly by E. O. Merchant, F. L. Hawes and W. W. Bays, is full of valuable information, systematically arranged and written with judgment and snap. The successive chapters deal with inorganic nitrates and ammoniates, organic ammoniates, phosphates, potash salts, and mixed fertilizers. The technical, the commercial and the financial aspects are all fairly considered and skillfully interwoven. It constitutes a valuable contribution to the literature of this important industry, useful alike to the scientist and the farmer, the technologist and the business man. But it is an open question whether the report has not gone too far in divulging what might be considered "trade secrets" in fairness to the commercial interests concerned.

CURRENT MARKET REPORTS

The Iron and Steel Market

Germany's announcement of unrestricted submarine warfare, made public on the first of the month, was followed by a sudden and sharp decrease in inquiry for steel products. The market had already become relatively quiet in this respect in the fore part of December, on account of the German peace proposal, the close approach of the holidays and the influence that business engagements had already been made very far ahead. During January there had been no sign of the increase in market activity that usually follows the holiday period.

No noticeable decrease in the filing of specifications against old contracts followed the German announcement, nor was there any relaxation in the pressure exerted by buyers for heavier deliveries of material against old contracts. Buyers required time to reach conclusions as to what effect upon steel conditions would

be exerted by the probable consequences of Germany's action. Their conduct showed clearly that it was purely a case of taking time to consider. They would not make new engagements and they would not relax their efforts to continue the business they were conducting.

What occurred was exactly what would be expected of the steel market. It is sensitive in its way, but it is not sensitive like the non-ferrous metal market in respect to exhibiting price fluctuations in accordance with current news.

Two influences of opposing character were to be weighed. If the promised submarine campaign were a success our iron and steel exports would be greatly reduced. They were largely to points in the prescribed area, and there was a possibility of exports to South America and Canada being curtailed. In January the export movement involved, directly and indirectly, about 20 per cent of the steel production. An increase of 10 per cent in the domestic supply might have quite an effect.

On the other hand preparations by the United States for war would result in the placing of some rush orders for steel, and the steel producers were all perfectly ready to give such orders all the precedence desired. As it would be the height of inefficiency in such circumstances to fill such orders at the expense of deliveries to those already engaged in fighting the possible enemy of the United States, it would be domestic deliveries that would be delayed in consequence of the new orders.

CURTAILED PRODUCTION

Transportation conditions as affecting the production and shipment of steel were showing signs of slight improvement when a blizzard on Sunday, Feb. 4, swept over the Central West, in a territory producing at least half the country's iron and steel. Instantly railroad traffic was greatly impeded. Car supplies greatly decreased and the dispatch of loaded cars suffered. The chief disturbance, however, was in the Connellsville coke region, coke shipments in the week following the blizzard being probably no more than one-half the requirements of the tributary blast furnaces. Pig iron production in the region affected was already 20 per cent or more below normal and promised to drop to 50 per cent or less. Steel interests which for weeks had been considering themselves fortunate in having reserves of scrap and pig iron to draw upon were confronted with the prospect that these reserves would run out long before transportation conditions became such as to permit normal production of pig iron.

The cold snap froze up the steel mills badly and for a few days production was greatly restricted in some departments from that cause alone. Nearly all natural gas was shut off from the mills still using it, being required for domestic consumers, who by common practice are served first. A tin plate plant in the heart of the West Virginia gas field was closed because the available gas had to be piped to Pittsburgh and elsewhere for domestic consumption.

PIG IRON

Trends noticeable in January have developed farther. There is a more complete absence of interest on the part of consumers in second half deliveries. This is proved conclusively by the existence of an unprecedented condition, that in practically all northern consuming territory southern foundry pig iron is available for second half delivery at prices many dollars a ton below prices the northern furnaces would regard as proper prices in case they were called upon to quote. Their inquiries are confined to early deliveries and early deliveries alone can they sell. To quote lower prices for forward de-

liveries would only embarrass them in making prompt sales. For illustration, the last important sales of valley pig iron for second half delivery, made some time ago, were at \$30, valley, for foundry or basic. Of late the furnaces have been obtaining \$33 to \$35 for small lots of prompt iron, which would be \$33.95 to \$34.95 delivered Pittsburgh, while for second half delivery Southern foundry iron is available at not over \$24, Birmingham, or \$28.55 delivered Pittsburgh. It is available for prompt shipment at the same price, but delivery would be very uncertain on account of the long haul. The normal pig iron market is one for forward deliveries and now there is no such market.

Export pig iron inquiry has diminished greatly. As the heavy export demand had a great deal to do with advancing and maintaining pig iron prices the new international conditions impose even more conservatism upon pig iron buyers than upon steel buyers.

STEEL

About February 1 a sale of 3000 tons of soft, open-hearth billets was made at \$65, f.o.b. maker's mill, Pittsburgh district. Transactions are few and far between and this one is probably representative of the market as far as there is a market.

Finished steel prices are firm all along the line. The advance in shapes and plates of \$3 a ton made by most of the mills in January has become general and prices for delivery at mill convenience may be quoted at 3c. for bars, 3.25c. for shapes and 3.75c. for plates. Large premiums rule on plates for earlier delivery, and small premiums on bars and shapes. Sheets and wire products are steady, with suspicions on the part of buyers that the producers are not sold up as fully as appeared a month ago to be the case. Tin plate is practically unobtainable, with \$8 bid in some instances. The mills are sold very fully to July 1 on tin plate and are altogether indisposed to consider the matter of prices for second half.

Non-Ferrous Metal Market

Feb. 8.—The disturbed international conditions have not caused very great changes at the present writing excepting in tin, which has gone higher in a somewhat excited market. Copper is slightly higher on heavier inquiry and antimony is scarce and higher. Spelter and lead are firm and practically unchanged.

Copper.—Sellers have been extremely shy for the greater part of the last two weeks, and little copper has been offered for early delivery. Electrolytic was offered at 33.50 on Jan. 29, at 33.00 on Feb. 1, and at 34.50 on Feb. 7. Lake has been running about 1 cent under this price. Exports in January were 23,511 tons. On Feb. 7 more inquiry was shown than previously and prices went up.

Tin.—As is to be expected from a market depending on foreign shipping, the tin market is unsettled and no one knows what will happen from one day to the next. There has been considerable activity in Banca tin at prices ranging from 44.50 on Jan. 30 to 51.00 cents on Feb. 7. The New York Metal Exchange gives deliveries for January at 7177 tons, of which 5200 tons were at Atlantic ports and 1977 tons at Pacific ports. This is 1200 tons above the record. Straits is quoted at 55.00 cents.

Lead.—On Jan. 29 the trust price was advanced to 8.00 cents. Independents have been asking from 7½ to 1.00 cent above the trust for some time, and the raise was not unexpected. Lead is scarce and there has been practically no market on spot. At present independents are asking 8.50 to 9.00 cents, prompt delivery.

Spelter.—Ore prices were advanced on Jan. 29, and this was followed by an advance in the metal to 11.05 cents, New York. It was reported on Jan. 31 that Great Britain would not buy any more spelter here, but the report had little effect. Spelter is now quoted at 10.55, New York, for prompt shipment.

Other Metals.—Antimony has become very scarce and has jumped from 23.00 cents on Jan. 29 to 32.00 cents on Feb. 7. Aluminium is now quoted at 57.00 to 59.00 cents, magnesium is down to \$3.00, electrolytic nickel is 50.00 cents, cadmium \$1.50, quicksilver \$100.00, platinum \$100.00, cobalt \$1.50, and silver 77%.

Chemical Market

Should the diplomatic break with Germany eventuate into open hostilities the chemical markets, particularly the coal tar division, will of course attract national attention. At the moment of writing sufficient time has not elapsed to effect material changes. Sellers, however, have adopted a very cautious attitude and the general tendency is to hold off pending developments.

Benzol has been subjected to considerable activity during the interval and the general asking rate of sellers has been on a higher level than when we last reported. One producer has been a disturbing influence, however, and some of their output was offered at a price considerably under the general market. However, only the most favored buyers could secure this material and it is believed that most of this product has now been sold. The largest selling interest has been accepting contracts over the three-year period with a guarantee against declines. It is estimated that the production of benzol at the present time is approximately 40,000,000 gal. yearly.

The *toluol* situation has become very interesting. In view of the probability of the American government shortly coming into the market for supplies of T. N. T. the general tendency is to hold supplies and there is a pronounced speculative interest present that is attempting to secure such supplies that may be available at attractive prices.

Again with *phenol*, the possibility of large orders for picric acid developing has once more created a firmer feeling in this market after a pronounced weak tendency for the past two weeks. Offerings from the middle West had resulted in the lowest prices that have prevailed for a long time and in consequence Eastern producers were compelled to meet this competition.

Aniline oil, however, has maintained an unusual degree of firmness during the interval and this situation was not in any way a reflection of political conditions. There are approximately 45 plants equipped with apparatus for the manufacture of aniline oil or its homologues in this country and the actual producers at the moment do not probably exceed 15. This is due to the unusually low prices that have been prevailing of late making it possible for only the most favorably situated from the raw material viewpoint to manufacture profitably. The production has decreased largely and a large number of export orders have reached this market of late resulting in an advance of more than 5 cents per lb. during the fortnight.

Ortho and *para toluidine* have become scarce with prices high as a result of the restricted production and the difficulty of separation. *Toluidine* mixture has been made in a fair way but unseparated has found but limited markets. A production of *toluidine* is announced by a prominent company, which has heretofore principally confined its operations to *alpha-naphthylamine*. Commercial *toluidine* base is held at \$3 for prompt delivery with producers not open for contracts at this time.

H acid (the amidonaphthol disulphonic acid 1:8:3:6) continues to attract a vast amount of attention. There is but little doubt that with the endless discussion of this product there will be a number of producers within the year. Already a production is announced for the near future by two entirely new factors who have not heretofore figured in this field.

Heavy Chemicals.—The possibility of restricted exports has generally tended to lower prices in this department of the industry. Products such as *copper sulphate*, which depend to a large degree on the export trade for their stability, slumped rather sharply. Weakness still prevails and general conditions are unsettled.

Caustic soda and *soda ash* have been working rather well in unison. The break with Germany resulted in a sharp decline in the former product but during the intervening few days there has been some quiet important buying and the general tendency at the moment of writing is to a recovery of lost values.

Glycerine has naturally been subject to much attention as a result of the international situation and an advance of several points has already been scored. The situation in this product is always more or less under stable control and a firmer market is likely. *Formaldehyde* has been scarce and considerable business has passed for domestic and export account.

Owing to the more liberal offerings of *cyanides* from abroad the situation has eased off considerably. The domestic situation is tight but as most material offered of late has been in speculative hands these interests have weakened in the face of liberal foreign offers principally from Japan.

In pharmaceuticals, *citric acid* and *citrates* have advanced sharply in face of the probability of more than an usual brisk spring demand. *Mercury* and *mercurials* have also advanced as has *cream of tartar*.

Interesting developments are expected in the market during the next few weeks and to-day's prices have but little meaning or value to-morrow. The crisis that has developed finds the chemical trade generally in better shape to assist the national government than ever before and already a number of the leading chemical manufacturers have offered the facilities of their plants to Washington.

General Chemicals

WHOLESALE PRICES IN NEW YORK MARKET FEBRUARY 7, 1917

Acetone, Drums	lb.	23	..23 1/2
Acid, acetic, 28 per cent.	100 lb.	3.25	..3.50
Acetic, 56 per cent.	100 lb.	6.75	..7.00
Acetic, glacial, 99 1/2 per cent, carboys	lb.	22	..23
Boric, crystals	lb.	11 1/2	..11 3/4
Citric, crystals	lb.	72	..80
Hydrochloric, commercial, 18 deg.	lb.	0.11 1/2	..0.11 1/2

INDUSTRIAL

Financial, Construction and Manufacturers' News

Financial

Atlas Refining Company, Delaware, has been incorporated with a capital of \$150,000 to produce petroleum and its products. The incorporators are C. W. Kirkland, Muskogee, Okla.; P. W. Murray, Bridgeport, Conn.; J. P. Given, New York; E. Walter Mitchell, Brooklyn, and Count Thomas Devassay, Budapest, Austria-Hungary.

The Auto Products Company, Nashville, Tenn., has been incorporated with a capital of \$2,000. Incorporators are A. E. Potter, A. Odell, F. M. Kelly, J. C. Ransom, P. C. Bowers, S. C. Ewing, F. H. Turner, H. C. Tucker and W. H. Ewing. The company expects to make benzoic acid and other chemicals.

Canton Metal Products Company, Canton, Ohio, has been incorporated with a capital of \$1,000,000. Incorporated by H. G. Bow.

The Carbonate Copper Company, San Antonio, Tex., has been incorporated with a capital of \$10,000. The incorporators are E. L. Porch, W. Schertz and W. F. Miller.

The Carlo-Nitrate Company, Pittsburgh, Pa., has increased its capital from \$5,000,000 to \$7,500,000.

The Cincinnati Iron and Steel Company has increased its capital stock from \$400,000 to \$800,000.

The Clover Foundry Company, Muskegon, Mich., has been incorporated with \$50,000.

Coeur-d'Alene Copper Mining Company, Spokane, Wash., has been incorporated with a capital of \$25,000. The incorporators are E. A. Laing, L. Harvey, M. A. Schneider, Comstedt & Company, Inc., New York.

Comstedt & Company, Inc., New York, has been incorporated with a capital of \$100,000. The incorporators are G. L. R. Munson, H. Waddington, J. T. A. Comstedt, 120 Broadway. The company is authorized to conduct business in iron, steel, and metal work.

Copper Products Company, Augusta, Me., has been incorporated with a capital of \$250,000 to carry on a general business of foundry, machine shop, manufacturing, depositing metals on other metals, and other business. The incorporators are S. S. Stevens, Manchester, Mass.; H. P. Sweetser, Portland, E. C. Ramsdell, Boston; P. E. Coyle, A. P. Brewer, Portland.

Driggs Mfg. Corp., New York, has been incorporated with a capital of \$300,000 to engage in factory supplies, ammunition, explosives, marine craft, aeroplanes. The incorporators are W. Zane, W. Abramson, L. L. Driggs, Jr., 120 Broadway.

The Durham Iron Works, Inc., Durham, Va., has been incorporated with a capital of \$25,000 for general foundry and machine shops. The incorporators are W. R. Kreker, W. F. Muellerhoeen, and others.

The E. I. du Pont de Nemours Powder Company is said to have offered \$1,000,000 for the plants and business of Harrison Bros. & Company, Inc., The Harrison Bros. Company has large plants at Philadelphia and Paulsboro, N. J., and manufactures paints, pigments, and chemicals. It is also the owner of pyrite mines in Virginia. Russell S. Hubbard is president and general manager of the Harrison Bros. Company.

Eastern Chemical Company, Wilmington, Del., has been incorporated with a capital of \$200,000.

The Electric Chemical Company, Salisbury, N. C., has been incorporated with a capital of \$10,000. The incorporators are M. A. Hodgkin, C. L. Jurkley, and others.

M. M. Elish & Company, Inc., Manhattan, has been incorporated with a capital of \$25,000 to manufacture paper. The incorporators are M. M. Elish, 620 E. 26th Street, Brooklyn; L. H. Biglow, Jr., South Orange, N. J.; H. L. Gutterson, Beechmont Park, New Rochelle.

The Excelsior Chemical Company, Youngstown, Ohio, has been incorporated with a capital of \$15,000. The incorporators are J. W. Blackburn, J. P. Wilson, C. W. Osborne, F. J. Heim, R. B. Wilson.

J. B. Gathright Land Company, Louisville, Ky., has been incorporated with a capital of \$25,000 to deal in oil, gas and other mineral properties. Incorporators,

W. H. Field, Matt O'Doherty, J. S. Clark, H. Harrison.

The General Chemical Company doubled its net profits in 1916. The amount for the year ending Dec. 31, 1916, was \$12,481,826, compared with \$6,153,796 for the year ending Dec. 31, 1915.

Great American Refining Company, Indianapolis, Ind., has been incorporated in Delaware with a capital of \$10,000,000 to produce oil and its products. The incorporators are Jos. O. More, Orpheus L. Teague, L. E. Replige, all of Indianapolis.

Grasselli Chemical Company earnings were reported at \$9,935,000 for 1916, or slightly better than 70 per cent of the present common stock issue of \$13,913,000, after deducting the preferred stock dividend requirements. In 1915 the company earned \$4,859,000.

The Harley Company, Springfield, Mass., has been incorporated to manufacture machinery and tools with a capital of \$1,200,000. The incorporators are L. J. Harley, L. J. Harley, Jr., Chas. H. Beckwith, all of Springfield.

Holland Aniline Dye Company, Holland, Mich., has been incorporated with a capital of \$100,000. The \$200,000 stock recently placed on the market has been subscribed.

The Hollander Manufacturing Company, Cleveland, Ohio, has been incorporated with a capital of \$10,000 to deal in metal products. The incorporators are J. Hollander, L. Hollander, H. Schanberg, J. Holstein and J. Hudik.

Industrial Paint Works, Inc., Passaic, N. J., has been incorporated with a capital of \$100,000 to manufacture paints and painters' supplies. The incorporators are R. Huff, J. P. Salisbury, F. A. Katterson.

International Peroxide Company, Brooklyn, N. Y., has been incorporated with a capital of \$100,000 to deal in and manufacture chemicals. Incorporators, J. R. Levine, I. Heitler, W. Wisch, 45 Malta Street, Brooklyn.

The Iola Portland Cement Company, Iola, Kan., has been purchased by the Iola Portland Cement Company, a Pennsylvania corporation operating cement plants in Pennsylvania, Virginia, Indiana, Washington, Illinois and Mason City, Ia.

The new owners will continue the policy of increasing the efficiency of the Iola plant. The Iola Portland Cement Company, a 23, million concern with general offices in the Commerce Building, Kansas City, expended \$300,000 in modernizing the plant last year and a similar outlay is to be made this year.

H. Struckmann, J. J. Helm, R. A. Long, J. W. Perry and A. D. Bayles are among the Kansas City stockholders of the Iola Company. The largest stockholder has been the National Bank of Commerce of St. Louis.

The Iowa Pure Iron Company, De Moines, Iowa, has been incorporated with a capital of \$300,000 to deal and manufacture sheet iron metal products. Incorporators are H. L. Helsing, E. Bern, A. G. Helsing.

Kennecott-Barrett Copper Company, Seattle, Wash., has been incorporated with a capital of \$1,500,000. The incorporators are Geo. Meier, T. C. Brownlee, W. A. Gaines and Geo. A. Lee.

Kennecott Extension Copper Company, Wilmington, Del., has been incorporated with a capital of \$5,000,000 to prepare all kinds of metals and minerals for market. The incorporators are M. B. Rogers, L. A. Irwin, H. W. Davis, all of Wilmington.

Keystone Mfg. Company, New Kensington, Pa., has been incorporated with a capital of \$30,000 to manufacture various articles of iron, steel, etc. The incorporators are J. P. Posahon, M. G. Penney, C. J. Lange.

Lukens Steel Company, Coatesville, Pa., has been incorporated with a capital of \$10,000. Gustave T. Schnatz, Philadelphia, treasurer.

Mechanical Window Glass Company, Springdale, Pa., has been incorporated with a capital of \$5,000,000 to manufacture window plate glass. The incorporators are Geo. G. Debay, Springdale; Warren D.

Gump; Arnold, Pa., and H. L. Schenck, of Pittsburgh.

Michel-Bilodeau Chemical Company, San Francisco, Calif., has been incorporated with a capital of \$50,000 to deal in drugs, chemicals and toilet articles. The incorporators are H. Michel, L. Bilodeau, F. B. Canas-Marquis.

The National Chemical Company, Ltd., with offices in the People's Gas Bldg., Chicago, has recently been incorporated for \$1,250,000 in S. Dakota and Illinois. The company will manufacture potash and by-products from kelp. An exclusive concession by the Canadian Government on kelp beds at Pafco, Queen Charlotte Island, B. C., which are estimated to produce 1,000,000 tons of kelp annually. The company's holdings are also in an excellent fishing district and it is expected to make the returns from fish fertilizer an important part of the company's income. Mr. M. V. Coone is president and general manager; Mr. Geo. A. Schwabland, who has had much experience in the kelp industry, is the company's chemical engineer.

New Jersey Dyestuffs Corp., Jersey City, N. J., has been incorporated with a capital of \$25,000 to deal in dyestuffs and chemicals of all kinds. The incorporators are J. Schneider, N. Marcus, R. Rieser, of Hoboken.

Nicholson Furnace Mfg. Company has been incorporated in Delaware with a capital of \$200,000 to manufacture furnaces, stoves, etc. The incorporators are J. Fry, L. T. Hopkins, and George H. Harman, all of New York.

Nome Sunset Mines, Inc., Nome, Alaska, has been incorporated in Delaware with a capital of \$2,500,000 to engage in mining of all kinds. The incorporators are J. Tobin, A. F. McIntosh, Jas. Halpin.

The North & South American Oil Company, Wilmington, Del., has been incorporated with a capital of \$500,000 to deal in oil lands and mining properties.

Old Dominion Chemical Company, Inc., Yorktown, Va., has been incorporated with a capital of \$275,000 to manufacture chemicals. The incorporators are E. H. Christian and E. S. Bolen, both of Richmond.

The Penant Produce Company, Cleveland, Ohio, has been incorporated with a capital of \$1,000,000 to manufacture and sell metal products of all kinds. Incorporators are B. D. Stevenson, G. R. Stevenson, L. B. Foote, W. A. Thompson, A. J. Hudson, all of Cleveland.

Pole Star Copper Company, Salt Lake City, Utah, has been incorporated with a capital of \$1,500,000. The business of the company will be mining, milling, smelting, etc. The incorporators are H. E. Latter, N. P. Coffin and H. T. Farrow.

Renania Chemical Works, Inc., New York, has been incorporated with a capital of \$15,000 to manufacture and deal in chemicals and medicines. The incorporators are J. H. Hutton, G. A. Wortelman, J. V. Bendish, 17 South Street.

The Reward Chemical Company, Toledo, Ohio, has been incorporated with a capital of \$10,000. The incorporators are J. L. Greenbaum, A. A. Greenbaum, Christ. Hopp, L. J. Mechler, and Sadie N. Joyce.

Roseburgh Chemical Corp., Syracuse, N. Y., has been incorporated with a capital of \$50,000 to manufacture chemicals. The incorporators are J. E. Porter, T. Hiseock, R. M. Roseburgh.

Royal Dye Works, Inc., New York, has been incorporated with a capital of \$10,000 to deal in dyes and chemicals. The incorporators are E. P. Kamholz, L. Scorsone, W. Koenig, 25 Echo Road, New Rochelle.

Serenita Mining Company has been incorporated in Delaware with a capital of \$30,000 to explore for and mine minerals, etc. The incorporators are V. C. Rogardus, H. H. Walter, M. Friedberg, all of New York.

Shure White Chemical Company, Mayfield, Ky., has been incorporated with a capital of \$5,000 to manufacture chemicals. The incorporators are L. Evans, W. W. Evans and N. E. Thomas.

Stockholders of the Solvay Process Company will vote on Feb. 27 to increase the capital stock from \$10,000,000 to \$20,000,000. Of the increase \$2,000,000 is to be offered to the share owners for subscription on the basis of 20 per cent of their holdings, as of March 1.

Springfield Wall Paper & Paint Company, Springfield, Mass., has been incorporated with a capital of \$10,000. The incorporators are J. Howard Jones, Geo. W. Steele and W. H. McCarthy.

The Standard Gas Power Company, 17 Battery Place, New York, is undergoing

a reorganization which will take several months. Mr. Akerlund, formerly chief engineer, has formed a company to be known as Akerlund & Semmes, 17 Battery Place, New York, to carry on combustion engineering business. It is possible that this company may be included in the reorganization of the Standard Gas Power Company.

Standard Oil Gas Burner Company, Wilmington, Del., has been incorporated with a capital of \$30,000 for manufacture and sale of oil gas burners.

Steffanson & Company, Inc., New York, has been incorporated with a capital of \$100,000 to manufacture paper. Incorporators, C. Engel, R. N. Chambers, J. French, 59 Wall Street.

The Stockholders Mining Company, Portland, Me., has been incorporated with a capital of \$2,000,000 to engage in mining, quarrying, smelting, refining, copper, gold, silver and all kinds of ores, etc.

B. T. Tuttle and W. W. Gregory, of Roscoe, N. Y., have formed a partnership for the manufacture of dyes. A factory will be erected in the spring.

The Union Oil Company, of California, in its financial report for the year ending Dec. 31, 1916, shows the company to have had a most successful year. Net profits are given as \$7,200,000, or \$4,380,000 greater than 1915.

United Chemical Company, Pittsburgh, Pa., has been incorporated with a capital of \$5,000. Incorporator, Jas. D. White.

United States Chemical Company, New Haven, Conn., has been incorporated with a capital of \$50,000, to manufacture and deal in chemicals. The incorporators are J. H. Sheehan, D. M. Freeman, J. J. Dunlap, all of New Haven.

Utah Mineral Paint Company, Salt Lake City, Utah, has been incorporated with a capital of \$50,000. The incorporators are C. H. Barton, David Jensen and Geo. A. Barry. Headquarters will be in Ogden.

The Val Blatz Paint & Varnish Company, Louisville, Ky., has changed its name to the Blatz Company. It has increased its capital from \$10,000 to \$30,000.

Virginia-Tennessee Iron Corp., Clifton Forge, Va., has been incorporated with a capital of \$100,000. Incorporators, C. F. Sente, A. C. Ford, of Clifton Forge.

Wade Process Corp., New York, N. Y., has been incorporated with a capital of \$300,000 to deal in oils and greases. The incorporators are L. Vinton, C. Mason, J. M. Keating, 30 Church Street.

The West Texas Sulphur Company, a Delaware corporation, has been granted a permit to do business in Texas. The company has \$500,000 capital stock and has headquarters in Philadelphia. Texas headquarters are in Texas.

Williams & Ferguson, Inc., Terre Haute, Ind., has been incorporated with a capital of \$15,000 to manufacture and sell wall paper, glass and oils and other articles. The incorporators are J. R. Ferguson, John Williams, Chas. F. Williams.

Worth Steel Co., Wilmington, Del., has been incorporated with a capital of \$2,500,000 to manufacture and deal in iron, steel, manganese, etc. The incorporators are J. E. Worth, W. P. Worth, E. H. Worth, W. A. Worth, N. T. Entrekin, all of Coatesville, Pa.

Construction and Operation

Arizona

CASA GRANDE.—Plans are being prepared for erecting concentrating plant at Lake Shore mine south of Casa Grande. E. P. Ryan, Mgr.

Arkansas

FLIPPIN.—The Marion County Zinc Company began operation on its new concentrating plant, having a capacity of 200 tons a day.

California

BERKELEY.—The Macauley Foundry Company will enlarge its plant on land recently purchased. The San Francisco Concentrating Company will use a new half block recently purchased for storage purposes until work on the new factory is begun.

BERKELEY.—The Paraffine Paint Company will erect a million dollar linoleum factory, the first of its kind in the West. The factory will be devoted to the manufacture of linoleum. The cost will be \$250,000.

LOS ANGELES.—The American Trona Company has plans calling for the immedi-

ate expenditure of \$300,000. The large factory will be completed. A decision was recently handed down by Judge H. T. DeWahl in the Superior Court of San Bernardino County favorable to the corporation in a suit brought by Harry E. Lee and others. The decision gives clear title to 25,000 acres in San Bernardino County. The company will go ahead immediately with the completion of its huge potash refining plant at the harbor.

SACRAMENTO.—Plans for building a big mill on the Pacific Coast to convert sawdust into cellulose are being completed.

SONORA.—The Dutch-App Mines Company is planning the erection of a new milling plant at the App mine. In connection with the mill in operation at the Dutch mine, the plant will be among the largest in California. It is probable the flotation process will be employed to a large extent, and the Dutch embody this method recently installed at the Dutch mine has proved satisfactory.

STELTON.—The Warman Steel Castings Company of Redondo Beach will build a country here. The company has operated an electric furnace at Redondo since 1913.

Connecticut

BRIDGEPORT.—The Hamilton & De Loss Company will have its new factory ready by June 1, 1917, for the manufacture of metal stamps and presses. The company was recently formed, with \$100,000 capital, and has the following officers: H. H. Hamilton, president; W. E. Cutler, superintendent, and R. L. Leach, chief chemist and metallurgist.

Illinois

CHICAGO.—The Reider Foundry Company has purchased land at the southeast corner of Oakley Avenue and 35th Place and will erect a foundry, to cost \$30,000.

CHICAGO.—The Iroquois Iron Company will erect a new steel casting plant which will cost more than one million dollars. Work will be started at once and will be pushed to completion by the end of the year. The plant will have a capacity of about 50,000 tons a day and it will increase the company's output to 1300 tons daily. The plant will be located at South Chicago, at the mouth of the Calumet River.

VANDALIA.—The Ford Manufacturing Co., manufacturers of roofing materials and compounds, will build a new lathe plant, paper mill and power plant.

Iowa

GILMORE CITY.—Work on the 1000-barrel plant of the Fort Dodge Portland Cement Co. is approaching completion, and if no further serious delays are met in the receiving of supplies this plant will be manufacturing cement by the middle of the year. Mr. H. C. Lehigh, formerly chief chemist for the Lehigh P. C. Company at Mason City, is to be superintendent of this new mill.

MASON CITY.—Construction on the new 1,500,000-dollar beet sugar plant of the Northern Sugar Corporation is being pushed as rapidly as possible, though some delay is experienced in getting the structural steel.

Kentucky

JEFFERSONVILLE.—The Armour Fertilizer Company expects to start work on erecting a plant in the near future.

MIDDLEBORO.—A co-operative paper mill was proposed at a meeting of representative publishers from southeastern Kentucky and eastern Tennessee on Jan. 20.

Maryland

BALTIMORE.—The American Refractories Company, Joliet, Ill., will erect a plant here, to cost \$100,000.

BALTIMORE.—The Canton Company is planning the erection of a \$75,000 factory at Highlandtown for the Electrotype Zinc Company.

BALTIMORE.—Electrolytic Zinc Company, 16th St. and 2d Ave., with plant at Highlandtown, plans erecting \$75,000 plant in the same section.

BALTIMORE.—The Davison Chemical Company is contemplating erecting a large Machine shop that will cost \$100,000.

Massachusetts

NEW BEDFORD.—The Taunton-New Bedford Copper Company will rebuild plant recently destroyed by fire, with loss of \$275,000.

Michigan

MANISTEE.—Work on the new plant of the Fer Fildes Company, a \$300,000 concern, is advancing rapidly and is expected to be completed in three months.

REED CITY.—The Ex-Cel-O-Paint Company, capitalized at \$100,000, will begin active manufacturing operations in a short time at Marion. A new plant will be built.

Missouri

POPULAR BLUFF.—The Butler Iron Company, recently incorporated, will erect blast furnace, concentrating plant and chemical plant to cost about \$650,000. W. W. Meehling, pres., Rookery Bldg., Chicago, Ill.

ST. LOUIS.—The Missouri Plate Glass Company, with a capital of one and one-half millions, with the Valley Park Realty Company capitalized at half a million, have recently been incorporated and will undertake the manufacture of glass in Valley Park.

Montana

BUTTE.—A number of capitalists have prepared plans to build a paper pulp mill near Big Fork, in Montana. The paper pulp will be made from the Montana spruce, which abounds in the Flathead country. The incorporators of the new company are J. F. Jordan of the Partridge Company, Warner of the McGill-Warner Company of St. Paul; G. M. and L. S. Gillette of the Minneapolis Steel and Foundry Company; J. F. Jordan of the Partridge Company, Minneapolis, and W. P. Snow, of Big Fork, Mont.

Nebraska

ALLIANCE.—The Black Hills Mica Company has planned the erection of a mica refining plant here. The plant will be for splitting and grinding mica as obtained from the mines.

New Jersey

RAYONNE.—The Texas Company has taken over a large tract of land in Bayonne, fronting on Newark Bay, for a refinery.

LINDEN.—The American Cyanamid Company, 200 Fifth Ave., New York, has taken over the properties and plant of the Ammo-Phos. Company and will complete its plant at Linden. Several buildings are ready for use.

NEWARK.—The Central Dyestuff & Chemical Company, Plum Point Lane, will erect 4-story warehouse, 75 x 123 ft., cost \$30,000.

NEWARK.—The Western Manufacturing & Oil Company, a West Virginia corporation, have sold a vacant plot to the Upson-Wyton Company of New York, who will begin the erection of separate buildings for rope plant, galvanizing and warehouse purposes, covering about 30,000 square feet.

WHARTON.—The Wharton Steel Company has been bought by J. E. Replogle and will soon be placed under the direction of one of the best-known steel men. The property lies within thirty-five miles of seaport. Several millions will be spent on a new plant.

New York

COHOES.—The Cohoes Rolling Mills have been purchased by Albany interests. Plans are under way to enlarge the output and make additions, so that ultimately 3000 men will be employed. The company is capitalized at \$500,000.

DUNKIRK.—C. A. Friederich, formerly general manager of the Dunkirk Glass plant, is making plans for the establishment of a new glass plant in this city, which will make the third glass plant to be established here since last year.

ELMIRA.—The Elmira Foundry Company, incorporated, has secured options on a big plot of land. This property is not considered desirable for manufacturing until permission has been secured to close certain streets.

NIAGARA FALLS.—The new plant of Isco Chemical Company is operating successfully. The plant was begun on March 25, 1916, by the John W. Cowper Company of Buffalo. The cost of the plant was \$400,000 and it is located on Union St. and Royal Ave. There are nine buildings, equipped with the most modern and complete machinery and apparatus for the manufacture of caustic soda and bleaching powder. The company is connected with the Innis-Speiden Company of New York. The output is sold by this company, the demand being outside of the United States country now being in Russia and South America. Mr. Eben C. Speiden is general manager of the company. The plant has been operating since November 10 and now operates 24 hours per day.

Ohio

CLEVELAND.—Mr. Charles E. Sheehan of Worcester, Mass., will superintend the construction of the new \$400,000 main building of the National Malleable Iron Company to be erected at Woodhill Road and Quincy Ave., S. E.

CLEVELAND.—The National Malleable Castings Co., 7700 Platt Ave., will erect a plant at Belt Lane Rd. and Woodhill RR., costing about \$250,000.

EAST LIVERPOOL.—The National Drawn Steel Company has made a request for a portion of the city farm for an addition to their plant. The capital has been increased from \$100,000 to \$150,000.

MASSILLON.—The National Pressed Steel Company began the erection of the main building on Jan. 9. The company was recently incorporated for \$1,000,000. Mr. H. M. Naugle is general manager. All the machinery and equipment has been ordered.

NILES.—The Basic Steel Company plans the erection of another plant in the Mahoning Valley. W. A. Taylor of Niles is president of the company.

Oklahoma

DILWORTH.—Because of the shortage of natural gas in West Virginia, glass plants may go to other cities. Dilworth has 500,000 cubic feet of gas daily available.

OKLAHOMA CITY.—The Burdett Oxygen Company will begin operation of its Oklahoma plant, located at the Stock Yards Station, Oklahoma City, on Feb. 15, and will be in a position to furnish oxygen to users in that city. The plant is the first plant installed by the Burdett Company in the various industrial centers of the country.

Pennsylvania

ESSINGTON.—Announcement has just been made by the Westinghouse Electric & Mfg. Company that the plot of ground recently purchased at Essington, near Philadelphia, will form a new industrial center for the Westinghouse Electric International Corporation.

The new premises about 500 acres, with a frontage of approximately one mile on the Delaware River. Additional transportation facilities will be afforded by trucks from Philadelphia and Philadelphia and Reading Roads.

This new center will be devoted to the production of large apparatus, the first group of buildings being for power machinery, principally turbines, compressors and reduction gears. The initial development will cost in the neighborhood of \$5,000,000 or \$6,000,000, occupying about one-fifth of the entire plot. The group will consist of the following buildings: two large machine shops, an erecting shop for heavy machinery, forge shop, pattern and pattern-storage shop, and power house. Work will begin on these as soon as satisfactory building contracts can be let.

The number of employees to be engaged at the new plant has not as yet been definitely determined, but will number several thousand people, and undoubtedly will in the future equal the number employed at East Pittsburgh, representing over 20,000 people.

MARCUS HOOK.—The General Chemical Company has purchased two tracts of land, totaling some 100 acres, near Marcus Hook, and it is understood that in addition to a plant a number of houses for employees will be built.

NORTH PHILADELPHIA.—The Scientific Equipment Co., 2951 N. 27th St., Philadelphia, plans the erection of a 3-story warehouse, to cost \$200,000.

PITTSBURGH.—The Raymond Bros. Impact Pulverizer Co., Chicago, Ill., has sold seventeen of its largest roller mills to the Carnegie Steel Company. Representatives of the company are now in Pittsburgh during the last month installing the mills. They are used for pulverizing coal for open-hearth furnaces. Five of the mills were installed at Clairton and twelve at Homestead. Those at Clairton have been set up and put in operation, and those at Homestead are partly in operation.

POTTSVILLE.—The Eastern Steel Company will enlarge its plant in the spring. The company has recently completed several purchases of land.

SHARON.—The Knox Pressed and Welded Steel Company has acquired the Sharon plant for \$1,000,000. The plant has only been operated a short time in its present location, but has been rushed to capacity ever since being acquired.

SHREVEPORT.—The Caddo Oil and Refining Company have filed a mortgage here to-day in favor of the Commercial Trust Company of Philadelphia for \$1,000,000, to cover the purchase of nine local oil and refining companies. The new company will begin at once to expend \$500,000 for improvements and development of properties, which include large acreages in the Caddo and Red River districts.

South Carolina

COLUMBIA.—Mr. Lloyd H. Grandy will erect a paper pulp mill plant to handle 10 cords of wood a day.

COLUMBIA.—The Union Bleaching Company proposes to double the present size of its plant. Improvements will represent an outlay of \$250,000.

Tennessee

CLEVELAND.—The Dixie Foundry Company is enlarging its plant in order to triple its output. The company will manufacture light and medium gray iron castings.

KINGSPOUT.—The new glass manufacturing company, which will employ about 300 men, will erect its plant this year, at a cost of \$150,000. Another company, which will manufacture oak veneer, has located here.

Texas

HOUSTON.—The Sinclair Oil and Gas Corporation will build a 300-mile pipeline from the Haldon oil field in southern Oklahoma to Houston, Tex. The company will then have pipelines running from the Gulf of Mexico to the Great Lakes, the system being about 1500 miles long. A big refinery will also be built near Houston. The company has also gained the concession of 9,000,000 acres in Costa Rica.

Utah

SALT LAKE CITY.—The Cache Sugar Company has issued \$150,000 additional stock and planned the establishment of a sugar plant at Cornudas, Cache County, situated on the Utah-Idaho state line. The plant will cost about \$600,000. The company has a capital of \$800,000. Mr. J. A. Hendrickson of Logan is president; J. Will Knight, of Provo, is vice-president; Lon J. Haddock, Salt Lake, secretary.

Washington

TACOMA.—The Tacoma City Council has entered into contract with Morton Gregory, of 2113 North Anderson St., Tacoma, for the lease of 3300 sq. ft. of floor space on the Municipal Dock property for one year. This space will be used by Mr. Gregory for the manufacture of synthetic rubber. He has spent considerable time in experimenting upon his formula and this last year has tested it out in various laboratories, among others at the University of Washington, where it is claimed, one of the professors made synthetic rubber by following out his process. Work will be commenced as soon as machinery arrives from the East. The lease is protected by under patent rights, both in this country and abroad.

TACOMA.—The Bilwode Alloys Company, producers of electric furnace ferromanganese, has engaged W. K. Booth as consulting engineer. The company is enlarging its present plant at Tacoma and will manufacture ferrochrome, ferrotungsten and silico-manganese, in addition to ferromanganese. A one-ton tungsten furnace, a six-ton ferromanganese furnace and a five-ton ferrochrome furnace will be added.

SEATTLE.—The Rothert Process Steel Company, Joshua Green Bldg., Seattle, has contracted for the erection of four Wile steel mills for rolling or making steel direct from magnetite ore.

West Virginia

CABIN CREEK.—The Ohio Cities Gas Company has planned the erection of a half-million-dollar plant at the mouth of Cabin Creek, near the company's big oil pool in West Virginia. The plant will be used for the manufacture of salt. The territory is in the midst of what are said to be the best gas deposits, with a permanently favorable fuel supply. The plant will handle about 12,000 barrels of salt water daily and it is expected to produce 26,000 tons of salt, 136,000 pounds of bromine, 7000 tons of calcium magnesium chloride annually.

Canada

BRIDGEPORT.—The Canadian Chicago Bridge & Iron Works, with headquarters at 37 St. Andrew St., Chicago, Ill., plans the erection of another plant in the spring.

LADYSMITH. B. C.—The Ladysmith Smelter Company, formerly operated by the Tye Copper Company, an English concern, has been purchased by American capitalists, and \$100,000 will be spent on improvements.

Manufacturers' Notes

THE BRAINARD-FAIRCHILD ENGINEERING CO., 330 Old Colony Bldg., Chicago, has been organized for the purpose of giving engineering assistance in connection with mining and metallurgical operations where crushing and grinding work is necessary. Mr. Brainard is head of the Brainard Pulverizer Co., of the same address.

THE SEARCHLIGHT CO. of Chicago, Ill., has consolidated with the Air Reduction Co. of New York and the Chicago

offices of the Searchlight Co. will be moved East.

SPAIN WANTS CHEMICALS.—The Merchants' Association of New York, through its Foreign Trade Bureau, recently made inquiry regarding the market for oils and chemicals in Spain. Reply has been received from the Consul General of the United States.

"In acknowledging the receipt of your letter of Oct. 10, with reference to extending the foreign trade of a New York firm dealing in oils and chemicals," says the Consul General, "I have to inform you that there is at present a great demand for such goods in Spain."

Aniline Oils and Chemicals

"Aniline oils and chemicals for use in textile industries were formerly imported in large quantities and their lack is now keenly felt by many Spanish manufacturers. To give you a more concise idea of the situation I have tabulated for you a few of the important items in which this decrease is noticeable, showing the amounts imported during the first eight months of 1914 and the period just previous to the outbreak of the war, and during the corresponding period of 1916:

	1914 Metric tons	1916 Metric tons
Coconut, palm oil and vegetable table oils except oil	1,045	781
Vegetable products employed in medicine not given separately	199	90
Products of the animal kingdom employed in medicine	96	39
Vegetable dyeing extracts	2,564	2,043
Mineral products, prepared in lumps and those prepared with water	1,928	755
Colors derived from coal	839	137
Hydrochloric and sulphuric acids	209	20
Nitric acid	19	8
Sulpholeic and other similar acids	47	5
Chloride of calcium	2,543	445

Demand Is Strong

"The demand for drugs and chemicals in this district has been particularly marked during the last two months, many importers, manufacturers and dealers having applied at this office for the names and addresses of exporters in the United States. It has been said that if sufficient supplies of this class of merchandise cannot soon be received in Barcelona, several important industries will be obliged to restrict or even suspend work."

TANTORION NOT DUTABLE.—The United States Court of Customs Appeals in a test case brought by the Bethlehem Foundry & Machine Co. has found in favor of the importers in regard to a duty on tantorion.

The Collector classified the commodity as ferrosilicon, this calling for duty at the rate of 15 per cent. The Board of General Appraisers found in favor of the importers. The Government then appealed to the court for a review of the board's finding. It was shown at the trial that whereas ordinary pig iron contained around 4 per cent of silicon, the tantorion in controversy had as much as 14 per cent. This fact, the Collector explained, warranted the inclusion of the merchandise in the ferrosilicon class.

Judge Martin, in his decision for the court affirming the board, and thereby sustaining the importers, said the evidence showed that the tantorion was ferrosilicon, but essentially differed from it in character and use. The court remarked that pig iron was met with in the trade occasionally with as high a percentage of silicon as high as 16 per cent. It was accordingly held that, while the merchandise in controversy differed to some extent from the average ferrosilicon of commerce in respect to the proportion of silicon it contained, notwithstanding this fact, properly free under the pig iron paragraph.

NEW HOME OF AMERICAN TOOL & MACHINE CO.—The American Tool & Machine Co. dates the foundation of its business in 1843 and with continual enlargement has occupied various localities within the city limits of Boston. Incorporated in 1880, the shops were established at Hyde Park in 1874, and the office for the last twenty years have been at 109 Beach Street. The company perfected and introduced the Weston centrifuge in 1865. During this twenty years the business has greatly increased and the desirability of more modern offices has led to the removal to the Rice Building at 10 High Street.

To accommodate the trade requiring immediate delivery of many productions in power transmission and machine shop requirements a warehouse has been established at 124 Purchase Street, which will be the shipping address. The new offices will be opened Feb. 1.

EMBARGO ON CHEMICALS IN THE UNITED KINGDOM.—The usual general license at London has been renewed under date of January 20 that the following chemicals are under prohibition of exportation: Sulphate of ammonia, prohibited to all destinations; ammonia and its salts, whether simple or compound (except ammonium nitrate, perchlorate, sulphate, and sulphocyanide), to all non-British destinations. These include, in addition, "Ammonia and its salts, whether simple or compound (except ammonium nitrate, perchlorate, and sulphocyanide)," which products were under prohibition to all non-British destinations.

AMERICA'S GREATEST YEAR IN FOREIGN TRADE.—American exports for 1916 reached the unprecedented total of \$5,481,000,000. According to a statement issued to-day by the Bureau of Foreign and Domestic Commerce, of the Department of Commerce, this exceeds the total for 1915 by \$1,826,000,000 and the total for 1914 by \$1,077,000,000. Exports for December are announced as \$521,000,000, which exceeds the previous high monthly total by \$5,000,000. The December average for five years previous was \$263,000,000.

Imports in 1916 aggregated \$2,392,000,000, also a record total. For 1915 the total was \$1,779,000,000 and for 1912, the previous record year, \$1,818,000,000. December imports were valued at \$240,000,000, indicating a continuation of the recovery which set in during September last following the sharp decline from the large total of \$246,000,000 for June. For December, 1915, total imports were \$172,000,000 and the December average from 1911 to 1915 inclusive, \$153,000,000.

The year's export balance was \$3,089,000,000, as compared with \$1,776,000,000 for 1915 and \$2,456,000,000 for 1914. Imports totaled \$2,392,000,000 for 1916, as compared with \$1,818,000,000 for 1915 and \$1,779,000,000 for 1914 inclusive. The December favorable trade balance was \$316,000,000, compared with \$187,000,000 for December, 1915, and \$131,000,000 for December, 1914.

NITRATE OF SODA SHIPMENTS IN 1916.—The total shipments of nitrate of soda to American ports for 1916 was 1,225,637 tons, as against 772,190 tons for 1915.

SCHAEFFER & BUDENBERG ESTABLISHES A ST. LOUIS OFFICE.—The Schaeffer & Budenberg Mfg. Co. of Brooklyn, N. Y., makers of Columbia recording instruments, has announced the establishment of a selling office in St. Louis, Mo., under the direction of A. H. Reuter, who was formerly connected with the Chicago office. The principal offices of this company are now Brooklyn, N. Y.; Philadelphia, Pa.; Pittsburgh, Pa.; Chicago, Ill.; St. Louis, Mo.; Los Angeles, Cal.

TRAYLOR ENGINEERING CO. OPENS CHICAGO OFFICE.—The Traylor Engineering & Manufacturing Co. of Allentown, Pa., has opened a Chicago office at 144 Fisher Building. The office will be in charge of L. J. Hewitt, who for the past thirty-six years has been intimately identified with the stone crushing machinery business of the mid-West, and for the past twelve years has been representative of the Fowle & Moring Machinery Co. in that territory.

MACKINNON, HOLMES & CO. CHANGES MANAGEMENT.—Changes in the management of Mackinnon, Holmes & Co., Ltd., of Sherbrooke, Que., have recently taken place, caused by the retirement from the company of A. R. Holmes, who in the past has occupied the position of director and secretary-treasurer.

It is understood that J. W. Bowman, president, and G. D. Mackinnon, president and general manager, have purchased the holdings of A. R. Holmes and his friends, and new directors in the persons of Dr. A. W. Klein of Greenwich, Conn., M. J. Mackinnon and J. J. Nicol of Sherbrooke, Que., have been elected, with P. C. Johnston, secretary-treasurer.

The business will be continued as in the past under the management of G. D. Mackinnon, and it is understood the company is making extensive plans for future development.

This company has been particularly successful in its general business of structural steel and steel plate work, having one of the most complete machinery concerns in the country for these special lines. It has also been successful in the forging of shells for the Imperial Munitions Board, having a very complete and up-to-date plant for this special work.

MERRIMAC TAKES OVER COCHRANE CO.—The formal transfer of the plant and business of the Cochran Chemical Company to the Merrimac Chemical Company has taken place, the latter concern taking over also the personnel of both offices and factory management. The business of the Cochran company will continue without interruption. Business, however, will be carried on in the name of the Merrimac Chemical Company and all communications should be made to it at 40 Central Street, Boston, Mass.

SEVERAL DIRECTORS RESIGN FROM FEDERAL DYESTUFF CORPORATION.—George T. Bishop, president of the Federal Dyestuffs & Chemical Corporation, resigned this week from that office. George H. Schuler, assistant to Mr. Bishop, resigned at the same time. The resigning directors were Ralph L. Fuller, E. G. Tiltonson, Mark W. Potter and George A. Coulton. It is stated that other interests require the attention of these men. Mr. Bishop is now connected with Ralph L. Fuller & Co., of which Mr. Fuller is the president.

BIG YEAR IN OIL INDUSTRY.—At the annual meeting of the Standard Oil Co. of New Jersey, F. W. Keller, vice-president, said that the unexpected demand for petroleum products 1916 has been a prosperous year in all branches of the business. During the year total production exceeded that of 1915, and the Argentine production was greater than increased production, and this situation is being reflected by advancing prices in crude. The brisk demand for the past two years at the minimum has resulted in the Argentine in production of crude. Outside capital has been used largely in providing this excess and the demand has come, as they do with great regularity in this business, this new capital will be brought to a realizing sense that it is uneconomic to pay for prices for other production and refining capacity. However, concerns that have been conservatively operated will probably on account of the demand continue to enjoy prosperity during the current year.

THE FIRST NATIONAL BANK OF BOSTON OPENS BUENOS AIRES BRANCH.—Arrangements have been completed for the opening by this bank of a branch in Buenos Aires under the management of Noel F. Tribe, a banker of experience, who has resided in the Argentine for the past twenty years and is exceptionally well versed in South American financial and trade conditions. Mr. Tribe will return to Buenos Aires in the near future. The bank's coming month will be very glad to meet at the bank or correspond with those who may care to take advantage of the opportunity to do business with him details of South American business.

This branch was established to assist in building up the foreign trade between the United States and Argentina. As soon as this trade passes through the port of Boston, and as New England exporters and importers are so vitally interested in accurate foreign credit information and dependable financial arrangements, it seems appropriate that this bank extend its activities in this way for the general benefit of our foreign trade.

The First National Bank of Boston is already prominent in financing the foreign trade in the foreign field, having direct bank correspondents in all the financial centers of the commercial world. Due to these connections, which its foreign department has built up in the last fifteen years, soon after the war broke out it took the lead in the foreign trade in business transacted, leading all other banks in this respect.

The advantage of a direct branch in the Argentine is obvious not only to assist in building up foreign trade during the present unsettled trade conditions, but also as a matter of preparedness to assist American retailers and exporters in the percentage of present business as possible after the close of the war.

THE GULICK-HENDERSON COMPANY, consulting and inspecting engineers, announce the removal and consolidation of their general offices from 30 Church Street and 129 Broadway, New York, to 13-21 Park Row.

NITRATE SHORTAGE FEARED BY GREAT BRITAIN.—England fears a shortage of nitrate of soda unless large shipments are soon forthcoming from Chile. W. D. Moorhead & Co., of London, have published a review of the situation for the last half of 1916.

After noting the upward course of prices in Chile during the past six months, they say:

"The fact that even 1915 has shared in the business done at 8s 3d ordinary, and 8s 6d for refined per quintal, is strong evidence that, in some quarters at least, a hopeful view is taken of the industry when, presumably, war will be no more. We have no valid reason for condemning such a policy, but it might perhaps be just as well to exercise caution in the matter of far forward purchases. For, who knows what new features in the industry the necessities of war may have brought about. It is tolerably certain that, even if no new discovery has been made, the mere use of great deal of machinery for the manufacture of synthetic nitrate in Germany which may become, on the basis of its new capitalization, a formidable competitor to the Chilean article. Perhaps, however, the prices now obtaining for 1917 are almost more dangerous from a purchaser's point of view (apart from government purchases), being so much higher, German peace offers must tell upon the nerves of holders and producers when prices rise to giddy heights. So far as the first six months of the year are concerned, we think holders have little to fear unless they have failed to secure their freight, but afterwards there might be more danger, when in view of the fact that the export of Germany to bring about negotiations for peace."

"Twelve months ago some doubt existed as to the capacity of the market to cope with the increase which was taking place, but this fear has been set at rest during this past few months by the market's wonderful power of adjustment. The question is, how long will it last? Should the present rate of production be the maximum, it is hardly likely that it will be found to be too much until the year is over, and that is about all we can say."

The figures of production for the year are 63,300 quintals, against 38,123,000 the previous twelve months. Stocks in Chile at to-day's date are 1,000,000 quintals, a year ago, being about 16,300,000 quintals, against 17,099,000. Freight to-day are very nominal, quotations being about 10s to 150s per ton for sea or steam, but it is doubtful if one would be forthcoming at even 160s.

"The conclusions to be arrived at from these considerations is that nitrate in the immediate future cannot well be cheaper than it is to-day and it may very easily be dearer, nevertheless, barring sulphate of ammonia, which may be obtained in small doses, if indeed it can be had at all, it is probably cheaper than any other form of fertilizer obtainable. The pity is that supplies are so slender."

Manufacturers' Catalogs

DENVER ENGINEERING WORKS COMPANY. Denver, Colo., has issued Bulletin No. 1, January, 1917, dealing with the Dewco ball mills.

MANTOWOC ENGINEERING WORKS. Manitowoc, Wis., has issued a pamphlet describing the Manitowoc dryer.

THE SIDCO COMPANY OF AMERICA, Inc. 37-39 Broadway, New York City, have issued a little booklet "Pure Fused Silica," describing their products, which are made in America.

THE NATIONAL CHEMICAL COMPANY. People's Gas Building, Chicago, Ill., has issued a booklet on potash manufacture from kelp, dealing in its uses, industry and commercial value.

MESTA MACHINE COMPANY. Pittsburgh, Pa., has issued Bulletin "D," booklet on the Mesta automatic plate valves (Iversen Patent).

Other New Publications

THE RADIUM-URANIUM RATIO IN CARNOTITES. By S. C. Lind and C. F. Whittemore. Technical Paper 88, Mineral Technology 6, issued by the Department of the Interior, Bureau of Mines, January 1917.

ITS FUTURE. Chandler lecture at Columbia University. By William Francis Hillebrand, chief chemist of the Bureau of Standards, at Washington, published by the Columbia University Press, New York Agents, Lemeke & Buchner, New York.

BIBLIOGRAPHY OF RECENT LITERATURE ON FLOTATION OF ORES. Compiled by D. A. Lyon, O. C. Ruston, F. Lacey and S. C. Lewis. Technical Paper 35, published by the Department of the Interior, Bureau of Mines, January to June, 1916.

UNITED STATES GOVERNMENT SPECIFICATION FOR PORTLAND CEMENT. Third edition issued Jan. 18, 1917. Circular No. 33 of Bureau of Standards.

Efficiency and Legislation

In the engineering of a popular propaganda there is no more useful aid than a well known catch-word. In recent years one of the best words of this kind is "efficiency" which has been brought into considerable popularity by its association with such well advertised things as the manufacture of Ford cars, the German war machine, efficiency engineers, etc. So it naturally followed that those who professed to believe that the Falls of Niagara were running dry should use the efficiency motif in their propaganda. From this it would appear that the rapacious power companies and the greedy electrochemists were not only guilty of trying to ruin a great natural spectacle, but in order to do so were using the water in the most inefficient manner possible.

The great advantage of the efficiency argument was the element of truth contained in it. It is not so many years ago that just below the upper steel arch bridge at Niagara Falls there was a spectacular display of water going to waste and while to some this did not lack picturesque features, to others it suggested criminal waste, while to Mr. Taft and "the representative of the American Civic Association" it gave the impression of "the back yard of a house negligently kept." Certainly there was no denying that the water was not used efficiently. However, it should be observed that this water came from a power canal begun in the year 1853, long before modern hydro-electric construction had reached its present high state of development. Moreover the company owning the development was busily engaged in improving its construction as quickly as circumstances permitted and to-day a very high degree of efficiency has been reached.

As regards the other hydro-electric plant it must not be forgotten that when it was planned and its construction started more than a quarter of a century ago it was a unique development, involving new and difficult engineering problems demanding great courage to face successfully. Those responsible for its creation undoubtedly availed themselves of the best engineering ability to make the experiment successful and it certainly was not a failure. But with the knowledge gained in this pioneer work and with modern experience in hydro-electric design the water taken from the river could now be used with far higher efficiency. Indeed several years ago it would have been possible so to modify the construction of this plant that the water it uses would generate an amount of electric energy closely approaching that theoretically available.

As has been pointed out in these columns before, the plans for such a hydroelectric development have long been in existence, but their execution has been suc-

cessfully blocked by the propaganda of those who profess to be advocates of efficiency. With the addition of a relatively small amount of water to that at present diverted by this plant it would be possible to reconstruct it so as to make it capable of generating 200,000 hp. at the highest efficiency. The much more efficient use of the water in this way has, however, been successfully blocked by the Burton Act and the artificial extensions of its effect and thus the utterly deplorable present situation has come about and every one realizes that something has to be done.

Congress is now considering permanent legislation in reference to the diversion of the Niagara River. So far as the efficient use of the water allowed by the international treaty is concerned the proper course of legislation is obvious. The pioneers in the development, the plants now existing at Niagara Falls, should be enabled in the one case to use water to the full capacity for which it is constructed and in the other to use sufficient water to permit reconstruction so as to bring up the efficiency to the highest point attainable by engineering means.

We might well take an example from Canada where the ideal is the fullest development possible at the maximum efficiency. There a canal starting from the upper river will carry the water to Queenston Heights, thus taking advantage of the greatest head that can be obtained.

This also is the very ideal of the electrochemist since the future of his processes depends on a vastly increased production of electric energy. This should be the ideal of everyone professing a desire for preparedness for war and peace; but is this the ideal of the Washington politicians?

Our Export Trade

Much of the comment made on our export trade during the war tends to produce an exaggerated notion of its character and volume. There is distortion by a psychological influence, the painful increase in the cost of living suggesting scarcity, and scarcity in turn suggesting that the United States has been drained of the things which we, the people, want to buy at a reasonable cost.

Nearly all the statistics of merchandise exports presented in discussions of our foreign trade are in figures preceded by the dollar mark. There is little to suggest quantity; much to suggest value. A collateral fact is that the net vessel tonnage cleared from the United States in the fiscal year ended June 30, 1914, was 53,183,409 tons, while the amount cleared in the calendar year 1916 was 53,150,891 tons, or just the same. In each twelvemonth the vessels were no doubt laden to capacity.

The quantity, on the other hand, cannot have increased greatly. There may have been changes in the character of the merchandise, of course, by which goods of an average greater intrinsic value were shipped lately, and certainly the price per unit of the same goods has greatly advanced. It is unfortunate that with so many commodities it is impossible to present statistics repre-

senting quantities. When such are available they frequently fail to show the demand from the allied belligerents that one might expect. There are quantity statistics, for instance, showing the number of pairs of boots and shoes exported. There is an island near us, in which we take a fatherly interest, the "Pearl of the Antilles," and the ruthless statistics inform us that in 1916, as well as in December of that year, we shipped more pairs of boots and shoes to that island than we did to the next two countries, the United Kingdom and Italy, combined. Yet the cost of footwear in this country goes up.

Indeed, the statistics of vessel clearances show that destinations were much the same last year as in the twelvemonth before the war, about the same proportions to Canada, South America, Europe, and the other continents. There was a trifling decrease to Europe and a fair increase to Asia, which redistribution the Trans-Caucasian railway explains. The tonnage formerly going to Germany and Austria has been made up by the entente allies and that is about all that can be said in this respect.

As to the value of the trade there has also been a disposition to exaggerate. Making allowance for the relatively small merchandise trade balance in 1914, and other necessary corrections, we have grown richer with our foreign trade up to the beginning of this year by only about four billion dollars. Before a careful study was made there were estimates that five or six billions of American securities were held abroad and they were all expected to come back to us. Investigation showed, however, that the amount was considerably less than four billion, while only about one and a quarter billion has come back.

It is true that we have purchased of foreign securities about two and a quarter billion. That may seem like a large amount, but England alone has borrowed about eighteen billion. We are very far from being England's chief banker. As to gold, a distorted view may easily be obtained, because gold as a basis for currency is one thing and gold as a representative of wealth quite another thing. With the stream that has been poured into the country, we have not only more gold as a sum, but more gold per capita, than we had of all kinds of money two decades ago when our late Secretary of State refused to be crucified upon a cross of gold—because there was not enough of it. Our net gold imports in three years have been only about three-quarter billion dollars, which is a great deal for a circulating medium but does not represent much wealth. Our railroads alone are capitalized at 28 times as much. Let us as a nation keep our nether garments on and realize that we still must work. There is no escape from this conclusion.

No small part of our export trade has been in iron and steel. The value of iron and steel exports in 1916 was \$867,323,044, according to the Government classification, which does not include in the category agricultural implements, railway rolling stock (except locomotives), automobiles, etc., although these goods contain much iron and steel. The value stated was 16 per cent

of the total value of exports. On account of our very small imports of iron and steel, practically negligible, the contribution to the trade balance was much larger, 27 per cent.

A Little Homily on Reading and Writing

It was the first lecture in the class in modern history at a leading American college which turns out good men. Its degrees are highly valued for good and sufficient reasons. The professor stated that he had no ambition to make his class letter-perfect in the dates of history; what he hoped to do was to give them a broader vision of the affairs of to-day and a better understanding of reactions in the mass of humanity. We appear, he said, to be at the brink of war, and the immediate cause of it may be the drowning of one or more citizens. But that, he continued, will be but the incidental cause; the real causes go back a hundred years; there are mistakes that have been made; cardinal mistakes, egregious blunders which, when they were committed, seemed marvels of astuteness, but which are the real causes of the present calamity.

In order to give the subject more vital interest and to make it more memorable to them he would make his lectures chiefly biographical; but for this they would need to have in mind a reasonable historical background. So he proposed to recall to them certain books with which they were probably familiar or, if not, to make them a part of their collateral reading. The parts played by men of mark in the chess-game of the peoples would then be understood.

He wondered how many had read Chesterton's Victorian Age. The class was large, but only two had ever heard the name of Chesterton. These two had also read the book mentioned. Trevelyan's Garibaldi, and the Thousand and The Making of Italy were inquired into. Of the same two students one had read Garibaldi and the Thousand, but none of the others had ever heard of Trevelyan. Thayer's Life of Cavour was totally unheard of and so was Edmund Gosse's Father and Son just as well as Money Penny's Disraeli.

They did not even know Mr. Brittling. One of the particular two had read Samuel Butler's Way of All Flesh and the other had looked at the title of Erewhon, but nobody else had ever heard of Samuel Butler. And so he proceeded through a popular list of the real contributions to literature made during the past ten or fifteen years that are indicative of the folkways. They were terra incognita to all but the two students we have mentioned.

Of all the books spoken of it is doubtful if any member of his class would have failed to finish a single one of them had he once begun to read it. They just did not know about them. They were typical Americans of good stock with the exception of the two who knew a book or two. Of these the one who had the better reading in English was born in Warsaw, Russia, and had first learned Yiddish and then Polish while the other was a young German, interned by the war in this country.

What's the matter with those American boys? They are fine fellows, sound young men, good students and they promise well, but the fact that they are ignorant of the literature of their own language, that they have no nose for that which bids fair to be permanent, shows something wrong.

We have no desire to hold the two foreign students up as having greater merit than the others. It is doubtful even if they have read more; the difference in this respect is that they have read good books, while the others have read trash. They had the good luck to strike something worth while that the others did not know about. Surely there is just as much sport in Garibaldi's life as there is in the imaginary career of any Dare-devil Dick who ever dodged bullets or rode an ostrich in a musical comedy. The explanation, we think, is to be found in one of those sequelæ of democracy which need constant watching. The foreign students were brought up to recognize authority. This may, and again it may not, have inhibited their initiative and narrowed their vision—that is another question entirely.

The only point we desire to make here is that, being accustomed to recognize authority, they betook themselves to the best available source of information as to what books they should read. The others didn't want any highbrow stuff put over onto them, and so they followed the lure of the magazines with their blurbs. The result is, they are not equipped to study contemporary history or even to express themselves in measures of grace.

Complaints are heard on every hand of good and competent engineers who are lacking in the ability to make clear reports or to state conditions so that intelligent laymen can understand them. They can work, but they can neither talk nor write. Sometimes the development of a great undertaking depends wholly upon their ability to talk or to write, and here is where they fall down. So the demand has become general for a larger measure of cultural studies and consequently for more time to be devoted to engineering courses. More or less radical changes have been proposed in the courses, but it is a question whether the solution can be found at all in that way.

Far be it from us to decry the beauties of classic lore, the marvelous treasures of Greek literature or the fascination of Gothic Days and the Renaissance. But some boys must hurry, really hurry, and the opportunity is not given them to take an arts course. Nevertheless, for every one who has taken his engineering degree and who lacks adequate general culture to speak or write without shaming himself, we can point to one or more bachelors of art who are no better off. Slipping through Greek and Latin will not turn the trick. On the other hand, we venture to say that any boy who comes to college with an established taste for that which is well and competently said in literature will not be at loss for the means to express himself when the time comes, no matter how much he may have had to skip and skimp by force of circumstances.

Readers' Views and Comments

The Niagara Falls Power Famine

To the Editor of Metallurgical & Chemical Engineering

SIR:—The relations between the government, the people at large, and the electrochemical industries of Niagara Falls have never been publicly and adequately explained, as far as I can see.

The fundamental psychology of the situation is about this. The people or the state own by the right of eminent domain, the Falls. They have a certain enjoyment of them at present and it is their own way of enjoyment. Now, it is all theirs.

If on the other hand the Falls, all or in large part, were used for power, they would see only factory buildings. Then, none of it would be theirs.

If, however, these factories were opened to the public in such a way that no substantial harm were done to private interests, "the beauties of electrochemistry" could be seen and enjoyed by some means by the people; then in due course the people would allow of an increasingly greater use of the Falls. The solution though easy in theory would be very hard in practice, but it can be done by such very able men as operate at Niagara Falls. But to me this psychology is sound.

In addition, I suppose that a tax would be placed on the power, for the trend of government is socialistic, not on Marxian lines, but by Socialism by Taxation.

W. MCA. JOHNSON.

Hartford, Conn.

Research and Industry

To the Editor of Metallurgical & Chemical Engineering

SIR:—The comment in the paper of Dr. G. W. Thompson (issues of Jan. 15, p. 79, and Feb. 1, p. 149) on the personnel in the development of chemistry really involves the whole subject of research in chemistry and metallurgy. With such able introduction there should be discussion, which is part of his remedy, publicity.

Having spent a life in research involving contact with several large industrial bodies I may be permitted to present the fallacy of present industrial relations to invention or research, with a remedy, and aid in spreading the idea that inventors, industries, and as a consequence the people, are heavy losers, and handicapped in competition with more progressive nations, because of present conditions.

Our industrial corporations must finance research as they possess the only adequate capital and through them the country must get the practice and there must be profit to research and industry.

The industrial personnel is mentally a very different body from the research personnel. This is true both in the capitalists, salesmen and business whips that constitute the directorates, and in the engineers and superintendents and executives that conduct the manufacturing.

The mind that finds the way to do new and improved things must see visions that are entirely obscured to the minds that finance, direct, manufacture and market.

The university professor or the historian and statistician is not in the research class.

All these accept the results of research as existing, and depend upon it for future advance.

We must acknowledge the past existence and future necessity of a mentality that is necessary for civilization as it exists and must exist in any advance. Chemistry and metallurgy form a very large portion of this underlying creation.

It is ably said that the one thing that boards of directors cannot control or direct is invention. Let us define two or perhaps three kinds of invention or research.

First, we have the true scientific discoveries that are useful purely to the scientist, produced largely by our university professors, supported by salaries, and supplied with the adequate bench laboratory apparatus.

Second, we have the radical industrial invention that applies science, finds means and details, and requires in recent times large capital expenditures that are nowhere provided for; yet this is directly the basis of industry that earns dollars and means material saving in the efficiency of life. It is this class of practical invention that has the greatest dollar value and that is more especially the subject of this digest.

Third, we have the invention that maintains efficiency in present known industrial development, closely allied to testing and standardizing, and this department of research is attempted and represented by our many research equipments in universities and industrial laboratories.

The classifications mingle, and there are at least two examples where the second class of research is conducted by industries. But it may be said that a large part, perhaps more than half of the second class of invention, is derived from independent minds not corporation-ruled, as to where they must invent, or chained by the organization necessary in economical industrial practice.

These minds see the vision, design the details and describe the conditions, and appeal to an industry that is interested, to procure the perhaps large amount of money necessary to demonstrate. If they meet acceptance they are asked to assign all rights as a first step, and are offered a salary that may stop, and are promised some reward if successful, yet no definite time for test or degree of use or a tangible promise of any size is made irrespective of value in sight.

In all the forms offered to the inventor for development of research the control is demanded by capital, irrespective of the cash involved or the future prospects, and no adequate cash is promised to enable the inventor to perfect his demonstration on a convincing commercial basis.

The business end demands control of research development—the one thing it does not understand—and it holds the power to proclaim failure before the tests are half completed, and, if a success, it may squelch the invention or do with the minority as it chooses.

Outside of the business argument involving dollars which is always a war, let us consider the effect of this form of control over minds that are about to create a thing necessary for civilized progress—practical applied invention. The result of this control is to incapacitate research mentality and create a loss, and perhaps often a useless expense, simply because industry is trying to direct and govern research as it does direct manufacturing and salesmanship.

When research has completed its commercial demonstration, free from any dictation by business, then it is proper and right that business should have the entire direction as to the degree, time and means to be employed in the application.

There can and should be ample consultation, but the dictation and direction must be well defined, if we seek efficiency in results, and the reward of research must be its commercial creation, and the reward of business the profits of manufacture and sale. This is the pur-

pose of our patent laws. The community ultimately benefits. But how can we do this?

Mr. Thompson desires greater publicity so that there will be a popular demand for more recognition of research and he is entirely correct. But even if this is granted the dictation and impotent direction of the research mind by the business mind will produce as inefficient results in research attempts as would the direction of business by the research mind.

There are, of course, many solutions in practice and I will present one that seems in keeping with the times and about to be recognized as necessary. The incorporation of the Research Corporation of New York to impartially administer royalties has been successful and will be followed by many others on similar lines.

The recent decision of the Supreme Court in the flotation litigation shows that commercial invention put into practice will be protected.

But it would be much wiser if these valuable sustained patents were not held by private corporations solely for private gain, but were held by the inventor who would be sustained by the industries that desire to use the invention, while the royalties were administered in a mild, fair way by impartial boards. Such boards can be easily created as needed.

Large sums of money are needed and research demonstration must be on an adequate commercial scale, yet nothing is more demoralizing than an attempt to conduct research at a manufacturing plant or use the staff connected with manufacturing effort.

Large capital calls for union in research. Union research would mean that several manufacturers interested in lines that use some invention or series of inventions, went under contract to advance adequate sums of cash to a pure research corporation, which in turn would agree to try out and prove certain things desired, and perhaps others as discovered.

The impartial referee board would decide on the royalty, which is paid to the research corporation to sustain research and compensate the inventor and enable the patents to be defended in court. This condition in some form must arrive and it is much cheaper and a much better research incentive for industry to anticipate it and aid it than to fight private greed which will become possessed of inventions of value.

No inventor will hesitate to enter into an arrangement of this kind, and the abler ones will by necessity lead and direct. Business and capital must be kept out except in an assisting capacity.

The attitude of corporations is usually not intentionally to kill research, and men like Mr. Thompson are honest and sincere, whom any inventor could trust personally, but they are servants of an inert body not organized for research which body can only conduct research by the means of business they understand.

I have seen so much of what I state in my past thirty years of pure research effort in metallurgical lines that the exception will but prove the rule.

Let my advices not be misunderstood as though I was feeling that I underrate the industrial engineer or the operating staff, for in their line they are wonderfully able and absolutely necessary, but when they attempt to direct or conduct research the average is as much against them as when the research mind attempts to conduct manufacturing.

I trust I have brought out the great value of each type of mind, its necessary environment, and shown how easy it is to make each more efficient by a proper contract system of relations governed by a clearing house. Mr. Thompson, as I personally know him, freed from corporation cares would be one of those rarely constituted minds who could direct research.

Essex, Mass.

The Western Metallurgical Field

Mills

Throughout the mining districts of the North American continent new mills are being erected or plans made for the construction or enlargement of mills. This activity in the increase of the output of ore all over the country is a sure sign that both the mining and metallurgical industries anticipate a boom in their respective lines of business for the next few years.

The mill of the *A. R. G. Mining Company*. This is a new mill, operating in the Joplin district and is located on a tract off the Barrat land north of Duenweg. The mill is one of the most modern in the district, the crusher, rolls, hoppers, sludge tables, jigs and other machinery and equipment all being set on concrete base. This feature not only increases the life of the plant, but also gives a smoother running of the machinery. The jigs are composed of two four-cell roughers and one seven-cell cleaner. The sludge tables are run continually to catch the fine ore. The capacity of the plant is 400 tons per day. The ore treated is high-grade material, and the mill is so constructed as to eliminate all chat from the final product, which may run as high as 63 per cent metallic zinc.

Other innovations made in the Joplin district are: The rebuilding of the 200-ton mill of the *Near By Mining Company* and the erection of the new 300-ton mill of the *Adirondack Company*. The *Near By Mining Company* is reconstructing the L. J. Stephenson mill, which lies between Webb City and Carterville. The mill needs little changing, the main features being the installation of electric power instead of steam and the addition of a few sludge tables for handling the fine ore. The new mill of the *Adirondack Company* lies in the western part of the Joplin district, and the construction is well under way and is of the most modern type.

The *Midvale Minerals Plant* is now in active operation. The plant was erected at the cost of \$100,000 and treats 300 to 400 tons of lead-zinc tailings per day. The mill is retreating the dump of the U. S. smelter at Midvale, Utah, the tonnage of which is so large that it is impossible to estimate it with any degree of accuracy. Other indications of an increase in the output of metals in the State of Utah are the erection of a 250-ton mill on the property of the *Keystone Mine* and the contemplated erection of a mill on the property of the *O. K. Silver* of Indian Springs in Tooele County.

In Canada, too, a lively increase in activity is noticed. A new high-grade mill is in operation at *The Mining Corporation of Canada*. The plant is an addition to the mill of the *Cobalt Reduction Company*. Previous to this the slimes from the concentrator were cyanided in the low-grade cyanide plant, and the sand concentrates were sent to the smelter. From now on the sand con-

centrates will be treated in the new mill together with the high-grade ores from the mines of the corporation, and in a short time all the shipments of the Canadian Mining Corporation will be in the form of high-grade bullion, which will be marketed in London. The new plant differs from the two other high-grade plants in the camp in that amalgamation plays no part in the process nor is the ore crushed in cyanide solution. The ore is first slimed in a tube mill, and after a preliminary treatment in two stages is de-watered and washed on an Oliver filter, then given a cyanide treatment and again filtered on a second Oliver. The silver is precipitated from the solution by means of sodium sulphide instead of aluminium dust. The silver sulphide is de-sulphurized, pumped to filter presses and refined in reverberatory furnaces to a high grade bullion, which is cast in bars and shipped to England.

The installation of a new mill is also under consideration at the *Lake Shore Gold Mines, Ltd.* The plans are now being worked out, and as the road of approach is rather difficult, it has been decided to have the necessary machinery hauled as soon as possible, so that construction may be started in the early part of next summer. The *British Columbia Copper Company* at present is erecting an experimental mill on the Similkameen River, which will be used for the working out of a concentration process preliminary to the erection of a 2000-ton plant at the same place.

Copper

Prospective Increase of Copper Refining Facilities.—A serious phase in the stage of the metallurgy of copper has faced this country for several months, namely, that the mine and smelter output has by far out-run the refinery capacity. The copper producers, while having made epoch-making sales, may find difficulty in making the required deliveries in the near future unless steps are taken to increase the number and capacity of the refineries in the United States. Having realized this dilemma, the "Boston News Bureau" has made a thorough canvass of the refineries for statistics bringing forth the actual prevailing conditions, a summary of which may prove of value. The following tables indicate the present monthly and annual capacities of the various refineries, and also the same after having completed the contemplated improvements and enlargements. The output is given in pounds per month and pounds per year.

	Present		Prospective	
	Monthly	Annual	Monthly	Annual
Am. Smelt. & R.				
Cu.	76,000,000	912,000,000	115,000,000	1,380,000,000
Anaconda	55,000,000	660,000,000	60,000,000	720,000,000
Nicholas	35,000,000	420,000,000	40,000,000	480,000,000
U. S. Smelting	17,000,000	204,000,000	20,000,000	240,000,000
Balbach	5,000,000	60,000,000	5,000,000	60,000,000
Totals	188,000,000	2,256,000,000	240,000,000	2,880,000,000
	Monthly		Annual	
	Present	Prospective	Present	Prospective
American Smelt. & Ref. Co.	40,000,000	60,000,000	480,000,000	720,000,000
Baltimore	20,000,000	25,000,000	240,000,000	300,000,000
Perth Amboy	16,000,000	30,000,000	192,000,000	360,000,000
Tacoma				
Totals	76,000,000	115,000,000	912,000,000	1,380,000,000
Anaconda				
Haritan	35,000,000	40,000,000	420,000,000	480,000,000
Gt. Falls, new	15,000,000	15,000,000	180,000,000	180,000,000
Gt. Falls, old	5,000,000	5,000,000	60,000,000	60,000,000
Totals	55,000,000	60,000,000	660,000,000	720,000,000

These improvements, it is understood, will not be completed until about June, 1917, and a shortage in the delivery of the finished material is therefore anticipated by the producers.

Copper from Mine Water.—The Butte-Duluth leaching plant has resumed operations under the direction

of interests associated with the Ohio Copper Company of Utah. This plant originally recovered copper from mine waters by electrolysis of the sulphate solution. At present the copper is precipitated on iron scrap, giving as final product cement copper. This change from the electrolytic to the precipitation process is a marked advance in the economical handling of the mine waters, the electrolytic process having been one of the most expensive features of the Butte-Duluth plant. The iron used in the form of scrap iron, tin cans, etc., is collected throughout the vicinity and thrown into the troughs through which the mine waters circulate. It might be suggested in this place that in case of a shortage of scrap iron, etc., spongy iron would prove of great value.

Platinum

Platinum Indications in Colorado.—The metal platinum so much desired in some of the chemical industries at the present is valued so highly that there is much interest in locating new sources for the production of this valuable element. At present there is undoubtedly a shortage in this country in metallic platinum and its salts, due to the fact that by far the largest amount of the world's platinum comes from Russia. Only a very small amount of platinum is produced in this country, and that comes mainly from the gold and silver bullion refineries. A. Lynn de Spain, chief chemist of the Burnhart Laboratories of Denver, states that platinum is found in the auriferous sands of the Iron Hill placer at Como, Col. In these sands the platinum is mechanically combined with magnetite. There is no doubt whatever that platinum also occurs in other localities of the State, as, for instance, in the black sands of Clear Creek. Little or no attention has been paid to the finding of platinum in Colorado, first because the rich gold finds have completely obliterated the importance of the other rare metals, and secondly, due to the fact that the average prospector is unable to recognize the metal or ores carrying the platinum. It is therefore essential that more attention be given to spread the characteristics of this metal so as to instigate the search for this metal by the prospectors.

Ozokerite

Ozokerite Plant at Soldier Summit, Utah.—Previous to the European war practically all of the ozokerite used in the industries came from the province of Boryslau, Galicia, Austria. Although it was known since 1879 that ozokerite occurred near Soldier Summit and near Colton, Utah, little was done to develop these resources, due to the fact that it was impossible to compete with the Austrian output. Since the outbreak of the war, Austrian ozokerite is no longer on the market, and as this product has a great field of application the home sources and their successful operation became an item of paramount interest. The only known commercial deposit of this valuable material in the United States lies in Wasatch County, Utah. This deposit is approximately 2 miles in width and 12 miles in length. Further development indicates that the deposit also possesses great depth. The ozokerite occurs in fissure and brecciated zones caused by fracturing of the rocks. The deposits enlarge from mere films to 6 and 8 in., while deposits as thick as 3 ft. have been found. The country rock, as a general rule, is sandstone, while the fractured zone ranges from 10 to 200 ft. in width, the brecciated zone being permeated with seams, gashes, bunches and even bodies of practically pure ozokerite wax.

According to Heath M. Robinson, the Utah ozokerite is a mixture of hydrocarbons in various proportions, the exact nature of which is a subject of dispute. The

color of ozokerite varies from black or dark brown to light yellow, while some specimens of a greenish color have been found. It is plastic without being soft, and hard without being brittle. These latter qualities make it extremely valuable in some industries. The melting point of ozokerite lies between 58 deg. and 80 deg. C. It is soluble in ether, petroleum, benzine, turpentine and carbon bisulphide. Alkalies and the strongest of acids have no effect on ozokerite. It is an excellent non-conductor for electricity, and is therefore extensively used in making insulators. Being waterproof, it is used for lining tanks in which strong acid solutions are used. In the manufacture of candles ozokerite is used to give higher illuminating power. Wax figures and wax dolls are made of this material. Further applications for ozokerite are the manufacture of hard rubber, in electrolytyping, in making phonograph records, in the manufacture of buttons, shoe polish, waterproof crayons, etc.

Ceresin, the refined product of ozokerite, is a substitute for carnauba wax, and is used in the manufacture of floor polishes, wax pastes, shoe and leather polishes, molding mass for copper and silver plating, wax for insulating electric cables, and composition for waterproofing cartridges. It is also used in making sealing wax, ceresin marking pencils, vaseline, cosmolene, molded ceresin candles and dozens of other products of industry.

Considering the wide scope of application of ozokerite and the sudden disappearance from the market of the foreign product, it is not to be wondered at that enterprises were undertaken to develop our own resources. For a year past the Wasatch Ozokerite Company has been in operation at Soldier Summit, Utah, endeavoring to put on the market their product. The treatment required to produce pure ozokerite is very simple as such, the main improvements being mainly along mechanical lines. Initially the company employed large vats, into which the crushed raw material was placed and subjected to treatment with hot water. This heat was sufficient to release the ozokerite from the adhering impurities. The wax, on rising to the surface was then skimmed off and poured into molds and allowed to cool. In this form the product was ready for the market. This mode of procedure proved rather inefficient, so that at present the company is operating steam-jacketed tanks in the treatment of the crude material. A new change is now contemplated by the company, namely, the installation of a cold-water process. The first unit of this process will raise the capacity of the plant from 10 tons of crude material to 60 tons per day. After completion the plant is expected to handle 1000 tons of crude ozokerite per day. With the present capacity of 10 tons of raw material, the plant is producing 400 lb. of ozokerite wax per day, which finds a ready market at 30 to 60 cents per pound.

The industry is undoubtedly here to stay, as it has been found that the deposits are much more extensive than was originally surmised, while the Galician deposits are known to have decreased enormously, and have also been damaged by the war to such an extent as to make their reworking very difficult. In the meantime the commercial development of the field in this country has made it possible to produce ozokerite wax and its refined products so cheaply that the home production will be able to compete with Austria, even though the Galician deposits be again put into operation after the war.

Company Reports

Report of the Old Dominion Copper Mining & Smelting Co. for 1915.—Due to the heavy repairs required at the mill and to the flotation work the cost per ton for

concentration was higher in 1915 than in 1914. The costs were \$1.215 for 1915 as compared to 0.932 for 1914. Much experimental work was done on flotation, and it was finally decided to use the Mineral Separation machine, but continue the investigation on other machines. Changes have also been made in the concentrator to reduce the power cost. These changes were justified on considering that the copper recovery for 1915 was 85.27 per cent, as compared with 73.55 per cent for 1914. The accompanying table summarizes the concentrating operations for the years 1914 and 1915:

	1915		1914	
	Dry Tons	% Cu.	Dry Tons	% Cu.
O. D. ore.....	32,560	3.72	30,101	4.69
Custom ore.....	140,486	4.48	121,792	4.67
Total and average.....	173,046	4.34	151,893	4.67

A comparison of smelting costs for 1915 with the previous year shows as follows, based on tons new charge smelted:

	1915	1914
Tons charge smelted.....	\$2,755	\$2,669
	206,549	207,595

The main items causing the increased cost per ton for 1915 were labor, repairs and increase in cost of flux. The coke consumption decreased 6 cents per ton of charge.

The cost of converting per ton of fine copper produced in bullion in 1915 compares with the previous year as follows:

	1915	1914
Pounds blister copper produced.....	\$5.36	\$5.65
	27,960,091	30,448,901
Pounds fine copper produced.....	27,736,158	30,210,361

The costs were decreased during the year, notwithstanding the fact that there were 2,500,000 lb. less copper produced in 1915 than in 1914. The saving was largely effected in the items of repairs. The cost of handling bullion in yards has been appreciably reduced. Of interest is the fact that the converter shell that was blown in on June 27, 1913, finally came off the stand on Dec. 7, 1915, after having produced 70,800,000 lb. of bullion. Due to the fact that there was no reserve stand to relieve it, and that the entire matte production of the smelter was handled by this shell, its campaign constitutes a most remarkable record. The lining costs per ton for the recently removed shell were \$0.055 per ton of bullion, while the best results that could be obtained under the old acid type practice was \$1.80 per ton of bullion.

Eighty-First Meeting of Faraday Society.—The eighty-first ordinary meeting of the Faraday Society was held on Monday, Dec. 18, 1916, at the Institution of Electrical Engineers, London. Sir ROBERT HADFIELD, president, and subsequently Prof. ALFRED W. PORTER, presided at the meeting. The papers presented were as follows: "A Carbon Tube Furnace for Testing and Softening Points and Compressive Strengths of Refractories," by Ezer and Edgar A. Griffiths (National Physical Laboratory); "Do Equilibrium Solutions in Iron Possess Equal Resistances?" by E. D. Campbell (University of Michigan); "Grain-Growth in Deformed and Annealed Low-Carbon Steel," by Ralph R. Sherry (Detroit, Mich.); "The Union of Glass in Optical Contact by Heat Treatment," by R. G. Parker and A. J. Dalloway; "The Effect of Pressure on the Equilibrium Constant of a Reaction in a Dilute Solution," by W. C. McLewis.

Fellowship in Low-Temperature Coking.—The American Creosoting Company has established an industrial fellowship at the University of Illinois. They have supplied the necessary funds for erecting an experimental coking plant.

PHOTOGRAPH TAKEN ON EXCURSION TO WEST POINT

Annual Meeting of American Institute of Mining Engineers

The annual meeting of the American Institute of Mining Engineers was held in New York City from Monday, Feb. 19, to Thursday, Feb. 22, inclusive.

Technical sessions were held on both the mornings and afternoons of Monday, Tuesday, and Wednesday.

The annual business meeting was held on Tuesday morning. President Ricketts had been ill, and while he was present and on the platform he turned the chair over to Vice-President Prof. Joseph W. Richards. The minutes of the previous annual meeting and the various regular reports were read and passed. Dr. Ricketts said a few graceful words, but postponed the greater part of his speech for the banquet on Tuesday evening.

The result of the election of officers was announced as follows: President, Philip N. Moore of St. Louis, Mo.; vice-presidents, Charles W. Goodale and Mark L. Regua; directors, Robert M. Raymond, W. G. Miller, Allen H. Rogers, Howard M. Eavenson, and J. E. Johnson, Jr. Decision on the simplified spelling was reserved until the directors decide what to do with some 350 unmarked ballots.

Mr. Hennen Jennings read a short report on the activities of the Joseph A. Holmes Safety Association.

The presidential election this year furnished some real excitement for the members. When they received their ballots for marking they found not one name but two—one the regular candidate of the nominating committee and the other an independent whose name was placed on the ballot by virtue of his large number of petitioners. The race was very close, with Mr. Moore receiving something over 1200 votes and Mr. Sidney J. Jennings receiving between 1000 and 1100 votes.

The entertainment features started on Monday evening with a reunion smoker. The fifth floor of the Engineering Societies Building was crowded and the members were seated in groups according to the colleges which they represented. A treat was furnished in the form of moving pictures of the front in Europe, David H. Browne read some funny stories of boyhood days in Ireland, speeches were made by Messrs. Sidney Jennings, Philip N. Moore, R. M. Raymond and Herbert C. Hoover. Mr. Hoover was given a great reception.

The annual banquet on Tuesday evening at the Hotel Astor was preceded by a reception to Dr. and Mrs. L. D. Ricketts and Mr. and Mrs. H. C. Hoover as guests of honor. At the banquet, speeches were made by the retiring president, Dr. L. D. Ricketts, by the president-elect, Mr. P. N. Moore, and by Mr. H. C. Hoover. The speeches were brief and the time saved by the omission of the usual long after-dinner speeches was spent in after-dinner dancing, which proved very popular and enjoyable.

On Wednesday evening Dr. Herbert T. Kalmus gave an interesting exhibition and lecture together with experiments on a new method of projecting moving pictures in colors, known as the technicolor process. On Thursday an all-day excursion was made by special train to West Point. An exhibition of riding by cadets was witnessed in the morning, luncheon was served in Cullum Memorial Hall, followed by dancing, and speeches were listened to in the afternoon in the auditorium of the Hall.

An exceedingly attractive program of events was furnished for the ladies under the supervision of the ladies' committee during all the days of the meeting. Mrs. H. W. Hardinge was chairman and Mrs. Bradley Stoughton, secretary.

PHILIP N. MOORE
President American Institute of
Mining Engineers

Grain Growth in Metals

This subject was discussed in the session on Metallography Monday morning, at which H. M. BOYLSTON presided. Two papers by Prof. HENRY M. HOWE and one paper by Prof. ZAY JEFFRIES were read. Professor Howe's papers were read by Professor Campbell. Professor Howe's first paper on "Recrystallization After Plastic Deformation" was a discussion of a paper by Mathewson and Phillips on brass presented last year. His other paper was a discussion of Mr. Jeffries' present paper on "Grain Growth Phenomena in Metals." Mr. Jeffries' paper was also a discussion of Mathewson and Phillips' paper. Mr. Jeffries' paper gives a very clear explanation of the phenomena of grain growth, and states that for every metal there is a temperature (designated the germinative temperature by Professor Howe) at which grain growth commences. The germinative temperature decreases with increase in deformation, and coarsening is influenced by the rate of heating, being greatly retarded by passing quickly through the germinative range. Another important

OF THE AMERICAN INSTITUTE OF MINING ENGINEERS

point is that the rate of coarsening is greater for a higher germinative temperature.

In the discussion on this subject Mr. W. F. Ruder said he had previously considered grain growth to be a critical strain phenomenon. He cited an experiment corroborating the statement that the germinative temperature decreases with increase in plastic deformation. Mr. Carter said he had made some experiments on platinum-iridium alloys. With pure platinum recrystallization occurred at about 1000 deg. C., with platinum-iridium at 1100 deg. C. or over, depending on the percentage of iridium. At 30 per cent iridium the grain does not grow with continuous heating to the same size as in a 20 per cent iridium alloy. Prof. J. W. Richards thought that metallurgists would find a great deal in Professor Bragg's work on crystals to aid in this study. (An article on Professor Bragg's work appeared in this journal July 1, 1916, page 35.)

Tungsten-Molybdenum Alloys

Two papers on this subject were presented in the same metallographical session, one by ZAY JEFFRIES and one by F. A. FAHRENWALD. Professor Jeffries described a new method of determining the melting points of tungsten and molybdenum alloys. A summary of Professor Fahrenwald's paper follows:

1. By compressing the mixed reduced powders of tungsten and molybdenum into briquets and then heating with an electric current in an atmosphere of hydrogen, alloys of this series were prepared varying in composition from 100 per cent tungsten to 100 per cent molybdenum.
2. The solidus curve for the series was located by means of optical pyrometer temperature measurements and checked by comparing the fusing current with a standardized wattage-temperature curve.
3. The equilibrium diagram for this series shows no critical points, appearing as resistance fluctuations, corresponding to a separation of a new phase. Its construction has been based upon this fact and upon results of microscopical analysis.
4. Curves for hardness, and for equalizing temperatures, are smoothly convex, being typical of an uninterrupted series of solid solutions (mixed crystals).
5. As a result of thermal and microscopical analysis, the metals tungsten and molybdenum are reported to be completely isomorphous.
6. All alloys of this series are malleable and ductile under proper conditions.

In discussing Professor Jeffries' paper Professor J. W. Richards suggested that the logarithm of the wattage should be plotted against temperature instead of the wattage, thus giving a straight line instead of a curved line.

Milling and Smelting

This session was held on Monday afternoon, SIDNEY J. JENNINGS presiding. An interesting paper on "Magnetic Concentration of Low-Grade Magnetic Iron Ore" was presented by S. NORTON and S. LEFEVRE. The paper describes the Ball-Norton separators and discusses present practice at the plants of Witherbee, Sherman & Co. at Mineville, N. Y. Various other wet

and dry tests are described. The authors' summary is as follows:

The known and partially developed orebodies of New York and New Jersey could, if equipped with the best modern mining and milling machinery and using the best methods, produce at the present time 25,000 tons of 60 per cent iron ore per day. This can be delivered for an average freight charge of \$0.75 per ton from mill to tidewater. The operating cost of production should reach the "dollar rock" ideal of the Lake Superior Copper region, and the cost of mining and milling one ton of crude ore should be about \$1 for underground mining when handled in large quantities. The ratio of concentration would be two tons of crude per ton of concentrates for an average. There are reserves of magnetic ore sufficient to double the above production, and then last probably 100 years.

In discussing the paper Mr. George C. Foote of the Witherbee, Sherman Co. said that 25 per cent ore is being worked successfully at Mineville, and that an even break financially could be expected on 20 per cent ore. Low-phosphorus ores are growing scarcer, and it is interesting to note that the phosphorus in the crude magnetite is reduced to one-half by magnetic concentration. The 0.02 per cent ore at Mineville is concentrated to 0.01 per cent P and 60 per cent Fe.

Mr. Birkinbine said that it was not to be inferred from the paper that all ores could be concentrated for 11 cents per ton. A coarse ore easily granulated can be concentrated. For the past year he has studied the lean magnetites in the East. In one section of Pennsylvania he found five different ranges of ore, showing the great diversity in the character of the ore. A great deal of experimentation is necessary before deciding on a process of ore treatment.

A paper on "Rock Crushing at McGill University" was read by JOHN W. BELL. It describes a series of tests on rock crushing, showing that Rittinger's law gives a better criterion for different machines as to crushing efficiency than does Kick's law.

A paper on "Counter-Current Decantation" was presented by LUTHER B. EAMES. This paper was published in full in our issue of Jan. 15, 1917, page 94. It was discussed by J. V. N. DORR.

"The Function of Alumina in Slags" was the subject of a paper by CARL HENRICH, who dealt with the matter from the standpoint of the iron blast-furnace engineer. His chief conclusions were:

In slags containing larger quantities of alumina, the alumina should be considered as an acid, replacing silica, and not as a base.

The higher the percentage of alumina, the nearer the slag should approach a "singulo-silicaluminate," i.e., the nearer the oxygen ratio of the bases should come to the combined oxygen of the silica and alumina.

An increase in magnesia calls for a higher percentage of bases, while absences of magnesia, and a pure limestone as a flux, will permit an approach to a "bi-silicaluminate" slag.

The safe way will be to start with a "sesqui-siliculate" as the type of slag to be produced,

which is approximately the slag actually, successfully and involuntarily.

In the discussion Mr. A. S. Dwight said he did not think that Al_2O_3 should be considered either as an acid or as a base, but should be neutral, inert, non-combining, dissolving in the slag itself. In actual practice this was tried at El Paso in a lead furnace with good results, figuring alumina, fluorspar, and zinc oxide as inert constituents. He thinks experiments should be made on a large scale as well as in the laboratory in order to solve this question.

Mr. E. P. Mathewson said that in Colorado, running on high alumina ores from Cripple Creek, he left the alumina out of the calculations and got excellent results with a freely running slag. When calculating the alumina in, trouble was experienced.

Mr. Boggs said he had worked on slags where the $\text{MgO} + \text{Al}_2\text{O}_3$ ran up to 18 per cent in making a 55 per cent Cu matte. He found that by neglecting the Al_2O_3 below 10 per cent good results were obtained, but above that the slag would not run.

Prof. J. W. Richards said the title of the paper was too broad, as its subject matter referred only to alumina in iron blast furnace slags. Hence the qualifications do not apply to lead or copper furnaces. Mr. DWIGHT replied that the temperature in the lead blast furnace may not be high enough to form silicates of Al_2O_3 and Zn as in iron furnaces.

"The Viscosity of Blast Furnace Slags" was discussed in a paper by Dr. ALEX. L. FEILD of the Bureau of Mines. The paper described a method of measuring the viscosity. In the discussion W. McA. Johnson said he thought the paper too theoretical. Dr. Feild said no attempt had been made yet to make a works instrument, but that would come later. Prof. R. H. Richards, Prof. J. W. Richards, George K. Burgess and Mr. Guess also discussed the paper.

A paper on "Matte Granulation at Herculeum, Mo.," by S. P. LINDAU and H. B. SMITH was read for the authors by Arthur S. Dwight.

Silica Refractories

In the Tuesday morning session, over which Prof. HEINRICH RIES presided, an interesting paper on silica refractories by J. SPOTTS McDOWELL of the Harbison-Walker Refractories Co. was presented describing a series of elaborate studies on the silica refractories. Some interesting lantern slides were shown describing the main features of the work. A fuller account of the paper is reserved for a future issue.

In the discussion Prof. J. W. Richards said that there are probably twenty different circumstances under which brick are used and the scientific study is extremely valuable. He called attention to the electrical conductivity, which was not mentioned in the paper. Mr. Henry D. Hibbard said he had had experience with silica brick in melting steel where pieces of the brick broke off instead of dripping down as customary. He thought insufficient mixing of the raw materials entering the brick might cause this failure.

Iron Blast Furnace Practice

Four papers were presented at the Tuesday afternoon session on iron blast-furnace practice, at which Prof. JOSEPH W. RICHARDS presided.

Two papers were presented by Messrs. LINN BRADLEY, H. D. EGBERT and W. W. STRONG of the Research Corporation, New York City. The first paper discussed the advantages of using a gas of higher flame tempera-

ture with improved stove design, together with the electrical method of cleaning the gas. The authors' second paper presented suggestions for the construction of hot-blast stoves along the lines discussed in their first paper. An abstract of the second paper will be found on page 283 of this issue. In the discussion Mr. F. H. Willcox said that dry-hot cleaning will probably be used to a large extent in the future when the gas is to be used under boilers. Mr. Breyer of the N. J. Zinc Company said they had considerable success with Tyson washers, scrubbing the gas which goes to boilers and stoves. The gas contains zinc oxide fume. He thought asbestos bags would probably be good when the hot gases are to be used after passing through the bags. He said that Messrs. Frazer and Chalmers of England are developing the asbestos bag-house system for hot gases, and have made several installations.

A paper on "Calculations with Reference to the Use of Carbon in Modern American Blast Furnaces" was presented by HENRY PHELPS HOWLAND. The paper was read by title. A communicated discussion by Professor Mathesius of Charlottenburg was read by the chairman, who also discussed the paper.

The paper on "Potash as a By-product from the Blast Furnace" by R. J. WYSOR was the subject of a long abstract in our Feb. 15 issue, page 205. Mr. Wysor showed some samples of the products from various locations at the Bethlehem Steel Company's plant at Bethlehem. The paper was discussed by Dr. Unger of the Carnegie Steel Company, who said they had made investigations of potash at many points. They used Lake Superior ore, Ohio and Pennsylvania limestone and Pennsylvania coke. This is somewhat different from the burden of the Eastern furnaces. The potash which they found was either insoluble or only one-third water soluble, and not enough to pay for recovery. They are at present making experiments around furnaces making ferro-manganese and ferro-silicon. The paper was also discussed by Messrs. Riddel, Breyer, Huston and Roush.

Flotation Discussion

The flotation session on Tuesday afternoon was presided over by EDWARD P. MATHEWSON. There was only one paper on the program entitled "Notes on Flotation, 1917," by J. M. CALLOW of Salt Lake City. Mr. Callow was in New York, but unable to attend the meeting, being engaged in a patent suit. His paper was therefore presented by Mr. H. A. Megraw who dealt especially with the notes on the Magma Sulphide Filming Plant. We herewith give this part of Mr. Callow's paper practically in full:

MAGMA SULPHIDE FILMING PLANT

The process in use in this plant is covered by Schwarz's U. S. patent 807,501, which is the first disclosure of the use of a soluble sulphide for converting an oxide of a metal into a superficial sulphide, and afterward recovering it by a flotation process.

Our earliest experiments were made with H_2S gas as the filming agent. A plant of 25 tons daily capacity was built. In this the gas was applied to the pulp by introducing it into the bottom of an open tank, having a mixing agitator. The results were encouraging, but the consumption of gas prohibitive—as much as 8 or 10 lb. per ton. The ore treated was the tailings of the Magma sulphide mill, which at that time carried considerable oxides. Occasional recoveries of 60 per cent (of the total copper) were made, but the results were erratic owing to the difficulty of getting uniform filming of the pulp with this method of applying gas. Then followed an interval of several months when we used sodium sulphide, calcium sulphide, and calcium sulphohydrate in an endeavor to avoid the use of gas, on the assumption that it was objectionable owing to the danger of its poisoning the surrounding atmosphere. This was true when attempting to use it in an open tank, much of it being lost in the atmosphere. During this time a number of

theories were advanced, exploited, and abandoned. One of these was that natural and artificial sulphides could not be floated together, and that H_2S interfered with the flotation of the natural sulphides. Our experience now is that H_2S , in the proper quantity really promotes flotation of natural sulphides in company with the filmed oxides, and also that the nature of the oil, and whether the oiling is done before or after filming, and whichever plan is followed is merely a matter of convenience.

In treating Magma sulphide tails, in which the principal losses were sulphides, the introduction of the gas not only filmed the oxides present, a goodly percentage of which was recovered, but it also raised an entirely new crop of refractory sulphides. An all-sulphide sample of regular Magma ore was tested with and without H₂S.

The commercial plant was shut down and we again reverted to laboratory work, which resulted in our adherence to H_2S in preference to any other agent on this particular ore, and also to a complete change in our method of applying it. The plant was reconstructed, crushing machinery and additional cells added in accordance with the flow sheet shown in Fig. 1, for the purpose of treating Magma oxidized ores on a commercial scale.

which interferes with flotation, and can always be identified by its eye-burning properties. This is in a measure overcome by careful scrubbing, sulphur being precipitated in the scrubbers with free H_2S liberated.

The California crude oil has the following fractional analysis:

Specific gravity 0.9311 or 20.36 Bé. at 15 deg. C.

Flash point—open dish—108 deg. C.

Fractionation:

Temperatures	Distillate, C.c.
100 deg. C.—150 deg. C.	1.2
150 deg. C.—175 deg. C.	1.6
175 deg. C.—200 deg. C.	3.6
200 deg. C.—225 deg. C.	9.6
225 deg. C.—250 deg. C.	22.0
250 deg. C.—275 deg. C.	30.8
275 deg. C.—300 deg. C.	25.2

Free gas in a pulp is fatal to flotation, hence the use of the blowing cell at the head of the first flotation cell. Experiments indicate that heating the pulp slightly before gasing is beneficial.

The cost of manufacturing the gas by this method will, of course, vary greatly according to local conditions. Those at Magna are abnormal. Sulphur is costing nearly 3 c. to-day, and oil nearly 1 c. per pound, f. o. b. Superior, and costs on a basis of 30 tons per day, and maximum of 3 lb. per ton, stand as follows: 90 lb. of sulphur at 2.74 c., \$2.51; 225 lb. of oil at 0.914 c., \$2.16; total, \$4.77 = 15.25 c. per ton, or approximately 5 c. per ton for each pound of sulphur per ton required by the ore.

On Magma sulphide tails, the gas consumption varies from $\frac{1}{2}$ to $1\frac{1}{2}$ lb. sulphur per ton. On strictly carbonate ore, assaying 3 or 4 per cent copper, 3 lb. is an average figure, and on the latest test with a mixed carbonate and silicate ore, assaying from 4 to 5 per cent copper, 2 lb. of sulphur per ton. The fuel required for heating the retort is almost negligible. There are no cost figures, since so far we have been burning scrap lumber left over from construction. The labor item is unduly heavy since the retort is situated some 600 ft. away, and one man has to be held in reserve for the purpose. He could as easily make gas on one shift for 500 tons per day. With

TABLE 1.—COST

1000 lb. of sulphur at \$45 per ton	
= 2.25 c. per lb.	= \$22.50
2500 lb. of oil at \$1.75 per bbl.	
= 0.436 c. per lb.	= 11.00
1 man at \$4	= 4.00
Extra fuel for heating retort and sundry repairs	= 2.50
	Per day \$40.00

sulphur and oil at moderate prices on a 500-ton scale, using 2 lb. of sulphur per ton, my estimate of total gas cost is as given in Table I.

Thus the probable cost is 8 c. per ton of ore, or 4 c. per ton for each pound of sulphur required for the ore.

Other methods were tried—one using powdered coal in a separate retort instead of the oil mixture, and another in which the oil instead of being mixed with the sulphur was dripped into the sulphur retort with a force feed lubricator. The usual iron matte and sulphuric acid method

1	8 ft. by 14½ Root blower, No. 1 (400 cu. ft. at 5 lb.)	
1	7 by 14 Dodge crusher (1 shift only).....	
1	2-in. centrifugal gasing pump.....	20 hp.
1	4-in. diaphragm pump.....	
1	10-in. belt drag classifier.....	
1	Oil feeder.....	
1	Oil feeder.....	
		55 hp.

FIG. 1—FLOW SHEET MAGMA SULPHIDE FILMING PLANT

The gasing method used at present introduces the gas into the suction of a centrifugal pump in the manner indicated in the flow sheet. This has proved effective, greatly reducing the gas consumption, giving more uniform recoveries, and has removed all danger from the poisoning of the atmosphere; in fact, the commercial results now being obtained date from the first use of this expedient.

MANUFACTURE OF H₂S GAS

The present method of making H₂S gas is to heat sulphur and oil in a retort. Various proportions of sulphur and oil have been tried, our present proportions being 1 of sulphur to 2½ of oil. The temperature in the retort is kept at a uniform 300 deg. C. At times the making of gas has given considerable trouble, owing almost entirely to changes from time to time in the quality of the oil used. Satisfactory results have been obtained at all times with California crude oil, but Texas oil always gives trouble, making a gas containing what we believe to be hydrogen persulphide.

was also tried but none of these methods had anything to recommend them over the one adopted. Iron matte was never seriously considered on account of the recent high price of acid.

The flow sheet given in Fig. 1 is self-explanatory: The 6-ft. by 16-in. Hardinge ball mill has a capacity of 35 tons per day when loaded with balls requiring 35 hp., or 45 tons per day when loaded up to 50 hp. crushing from crusher run to 83 per cent — 150 mesh.

The power requirements are distributed as stated in Table II.

This is the equivalent of 37.6 hp.-hr. per ton, = 28 kw.-hr. per ton.

The plant is operated by four men for the three shifts, the extra man on day shift crushing the ore and hand sorting out any first-class ore there may be at the same time.

A general discussion on flotation followed. It was kept alive and rendered quite interesting enough through the energetic efforts of the chairman, Mr. Mathewson.

It was opened by Dr. Rudolf Gahl, whose long discussion was sent with Arizona enterprise by telegram and who answered some criticisms of his own former paper by Mr. Callow and in turn criticized some points of Mr. Callow's paper, particularly relating to the comparison of the Callow flotation machine and the Inspiration flotation machine. Dr. Gahl's long telegram was read in full by Mr. Robinson.

Mr. G. D. Van Arsdale expressed the opinion that ores should be divided for flotation into three classes; first, those requiring acidity of pulp; second, those requiring alkalinity of pulp, and, third, those requiring neutrality of pulp, and that there seems no doubt that this varying action is to be referred to the influence of the constituents of the gangue. He also brought out another important practical point, namely, the composition of mill waters and the effect of dissolved salts on flotation.

Mr. John V. N. Dorr read a discussion by Mr. E. R. Ramsey, relating to the handling of flotation concentrates and the use of the Dorr thickener and tray thickener.

Professor E. E. Free spoke on the theory of the flotation process and proposed the hypothesis that adsorbed films, formed previously to the application of the flotation oils, might explain many anomalies of flotation practice.

Professor J. W. Bell asked whether that would explain the necessity of using acid in many particular cases. Professor Free answered that no generalization of his hypothesis seems possible at present. Every case of adsorption has to stand on its own feet.

Mr. H. W. Dubois discussed flotation litigation. He asked: How can even the best courts as now constituted pass on such highly technical problems? Is it not like playing baseball with an umpire who has never seen the game? Does flotation really depend on the use of such a very small quantity of oil? Is there really a critical point in the amount of oil which makes the process effective? From his experience he concludes that there is no such critical point for certain classes of ore, though there may be for others. For certain classes of ore 2 or 3 or even 25 per cent. of oil will give as good results as less than 1 per cent of oil, and the use of the latter amount is merely a matter of economy.

Mr. G. D. Van Arsdale said he had never found a critical point nor did he see any reason for its existence. But certain apparatus may be better for certain amounts of oil.

Mr. J. V. N. Dorr referred to two Western companies which use more than 1 per cent of oil.

Mr. Mathewson told how in a particular case a flotation expert came and experimented for some weeks without conclusive results; when a little sulphuric acid was used it worked fine. Why? He also stated that excel-

lent results had been produced with more than 1 per cent of oil and that the use of less than 1 per cent of oil was simply a question of economy.

Professor R. H. Richards referred to flotation as a friend, not a rival of gravity concentration.

Mr. Dubois referred to bornite ore, which, according to Hoover, was difficult to float. But he found that acid helps, and his experiments showed that CO₂ bubbles attached themselves while the ordinary bubbles would not. Hence this is not the ordinary acid effect. Dr. Bell spoke of some similar experiments. Mr. H. W. Hardinge told a good story; Mr. Calbraith referred to mining as the fundamental industry, and after Mr. Dubois had pointed out that Japan had passed a law not to allow any flotation patents and that the fundamental U. S. patents for flotation had not been granted in Germany, the meeting adjourned.

Manufacture of Iron and Steel

Mr. Henry D. Hibbard presided at the Wednesday morning session devoted to the manufacture of iron and steel.

"The Seasoning of Castings" was the subject of a paper by RICHARD MOLDENKE. An abstract of this paper will be given in our next issue. Mr. Outerbridge, Jr., of Philadelphia gave an interesting discussion of this paper.

A paper on "The Significance of Manganese in American Steel Metallurgy" was read by F. W. WILLCOX.

A paper on "Roll Scale as a Factor in the Bessemer Process," by A. PATTON and F. N. SPELLER, was read by Mr. Speller.

A paper on "Temperature Measurements in Bessemer and Open-Hearth Practice" was read by GEORGE K. BURGESS.

A paper on "The Manufacture of Weldless Steel Tires for Locomotive and Car Wheels" was read by GUILLIAEM AERTSEN.

Metallography and Heat-Treatment of Steel

This session was held on Wednesday afternoon, ALBERT SAUVEUR presiding. The following papers were presented:

"Erosion of Guns—The Hardening of the Surface," Henry Fay.

"Notes on the Heat Treatment of High-Speed Steel Tools," A. E. Bellis and T. W. Hardy.

"Effect of Time in Reheating Hardened Steel Below the Critical Range," C. R. Hayward and S. S. Raymond.

"The Effect of Sulphur on Low-Carbon Steel," Carle R. Raymond.

"A Method for Distinguishing Sulphides from Oxides in the Metallography of Steel," George F. Comstock.

Professor Sauveur opened the discussion of Professor Fay's paper. He said that all the conditions necessary for case hardening were present in gun firing and that it should be taken into account. Mr. Hiram Maxim said a temperature of 4000 deg. Fahr. to 4500 deg. Fahr., was produced in a gun using nitrocellulose. Temperatures up to 6500 deg. Fahr., are obtained from mixtures of nitrocellulose and nitroglycerin. The products of combustion are under a pressure of 35,000 lb. per square inch. The caliber of the gun is increased 0.001 inch at every shot. Mr. Lawrence Addicks thought the thermal conductivity should be studied, as some steels have lower conductivity than others. Mr. Maxim didn't think there was time enough for much heat conductivity; Professor Richards said that by using alloys of iron with metals such as tungsten, boron, titanium, etc., which give a lower vapor tension, the life of the gun ought to be prolonged. Professor Fay replied to several questions.

Nitrate Industry in Chile

By I. Berkwood Hobsbawn

So much attention has been drawn in recent years to the rapidly approaching death of the Chilean nitrate industry that it seems very much like "flogging a dead horse" to draw the attention of chemists, metallurgists and chemical engineers to it. In spite of this approaching "calamity," a description of this industry and an indication of its "re-birth" will not come amiss during a period such as this, when the prime output of the industry is of such vital importance.

Nitrate of soda, the substance which lends itself so equally to man's needs for both his peaceful and his war-like arts, is met with in nature in enormous quantities in the arid zone between the slopes of the Andes in the north of Chile and the foothills to the sea. This tableland, varying in altitude from 3000 to 7000 ft. above sea level, has been sufficiently described from time to time to need no further location or description here, but for years it has been the center of the production of nitrate of soda for the world's fertilizer needs.

Since its use was brought to the notice of the world in 1809 by Taddeo Haenke, a German domiciled in Bolivia, the export of nitrate of soda has exceeded a total of 53,000,000 long tons, and the present output is in the neighborhood of 2,500,000 to 3,000,000 long tons per annum. It will be agreed on this basis that the Chilean nitrate industry is one of very huge proportions, and at the same time, it must be asserted, that apparently little is known about it by the world in general in proportion to its importance or size.

As the attention of this country is being drawn very markedly to the value of nitrate of soda, both as a fertilizer and for other less peaceful purposes, and as the so-called exhaustion of the deposits in Chile, due in 1921 according to the "authorities," has been indefinitely postponed, it is very opportune to describe for the American readers interested in this particular product how nitrate of soda is obtained from the crude deposits and, further, to indicate how American progress in other directions and industries is being used to attempt the modernization of the methods in use in Chile, and to reorganize completely the means of procuring the refining of so useful a product. It would perhaps be as well officially to refute once and for all the statement so widely circulated in this country and in Europe that the nitrate deposits in Chile are very rapidly becoming exhausted.

The official report recorded below is that of Mr. Francisco J. Castillo (the inspector general of the nitrate deposits for the Chilean Government), which was issued in November, 1913, by the Chilean Nitrate Committee of London, England, under the auspices of the Chilean Embassy in that country.

Nitrate of Soda Deposits in Chile

"According to the latest official report presented to the Chilean Government by Mr. Francisco J. Castillo, the inspector general of the nitrate deposits, the zone of nitrate-bearing grounds comprises 200,000 sq. km., of which so far only 5811 sq. km., that is to say, less than 3 per cent, are examined and their contents ascertained by excavation and test holes. These 5811 sq. km. belong to existing companies and private firms, and in part are still in the hands of the Chilean Government. The calculated contents of this 5811 sq. km. are 290,300,000 tons of nitrate of soda, of which up to the present 45,000,000 tons (1912) have been extracted and exported, leaving in the examined part of the area 245,300,000 tons of nitrate of soda, equal at the present

rate of production to a supply for a further hundred years. As the unexplored part is some thirty-four times larger than the explored grounds, it is safe to estimate that it contains altogether at least an equal quantity of nitrate of soda, and consequently the nitrate zone in Chile can certainly provide nitrate of soda for another 200 years at the present rate of production.

"The quantity of nitrate of soda in the examined grounds is subdivided as follows:

In the province of Tarapaca there remains.....	35,000,000 tons
In the Tocopilla District there remains.....	28,000,000 tons
In the Antofagasta (Central Dist.) there remains.....	32,000,000 tons
In the Antofagasta (Aguas Blancas) there remains.....	48,000,000 tons
In Chanaral and Copiapo there remains.....	8,300,000 tons
A total of	245,300,000 tons

"The inspector general of nitrate grounds in his report to the Chilean Government has arrived at these figures in the following way:

"In these examined grounds no raw material containing less than 11 per cent nitrate of soda has been taken into consideration, nor grounds where the thickness of the layer of raw material is less than 1 ft., except in the case of raw material of at least 25 per cent of nitrate of soda, where the thickness of 8 in. and above has been included.

"The superficial area of each portion of ground examined has been divided by the total number of test holes made in order to arrive at the area applicable to each test hole, and this consequently determines the total nitrate-bearing area.

"From this theoretical quantity of pure nitrate of soda resulting from the above operations, a reduction of 40 per cent has been made in order to provide for losses in extraction, manufacture, errors of calculation, etc. Of raw material of a lower grade vast quantities remain which have been excluded from these calculations because they cannot be profitably extracted under the present system of work, but as improvements are being constantly made there is every reason to assume that even this low-grade material will be worked when the richer qualities are exhausted."

These statements, therefore, conclusively show that there is no fear of the Chilean nitrate deposits being exhausted for 200 years on the present basis of output and present efficiency of plant.

Taking into consideration that during the last four years an enormous impetus has been given to development work in Chile, through one cause or another, and that many workers are engaged in attempting to apply the principles found successful in industries in other countries, it will be agreed that some measure of success attending these developments would not only increase the estimated 200 years in proportion to the increased efficiency which these new processes would give, but would also bring into consideration the material of less than 11 per cent, which at present is not included, by making it amenable to treatment.

This point does not need very much laboring for mining engineers to appreciate the huge quantities of material that will be brought into value if the process is able to use up anything above 5 per cent material. At the present day it is not only found advisable not to include 11 per cent and under in the estimated nitrate contents of the grounds, but more, in working these grounds, it is often impossible to take into the works material of 14 per cent and lower, and necessarily the raw material has to be hand-selected. In fact the limitations imposed upon the mining of nitrate of soda by the poor efficiency of the refining plants are such that where an average of 20-22 per cent nitrate is required for the refining plant very little material of less than 14 per cent can be used with richer material to make up the required average.

Under these circumstances, if a description of the actual work of the nitrate industry is given and an outline of the methods in use is drawn, subsequently followed by an indication of the direction in which it is hoped that higher efficiency shall be gained, it will then be appreciated what would be really effected by these changes, not only in regard to the methods of mining involved, but also to the operation of the whole of the industry itself.

The methods of refining nitrate of soda have been variously referred to as crude and primitive, but whereas these terms might well be applied to the actual methods of lixiviation and mining, the mechanical means for carrying out such do not come under these headings; in fact, were it not for the development of the mechanical side of the operations, it is very doubtful whether the industry could have been carried on to any profitable extent with the lower-grade material now in use.

In modern works the handling of the raw material and the generation of power for that purpose and for the disposal of the refuse has been developed on very modern lines. The methods of treatment of the raw material, however, do not yield a high efficiency for various reasons, and it is because of this low efficiency in the works that methods of mining of the raw material are very much restricted; in fact, take the average efficiency of the process as 50 per cent, and the refuse over all, accounting for 10 per cent nitrate, the minimum contents of nitrate in the raw material cannot, except in special instances, be less than 20 per cent. Twenty to 22 per cent is the general average of the material sent to the works for refining, and in order to gain this average ley of material from the grounds it is necessary to resort to hand-selection, such selection to a large extent depending upon the personal experience of the miner controlled by the general analysis performed in the factory. In this way the mining is costly and the percentage of nitrate taken out as raw material, out of the total of the deposits, comparatively low.

Raw nitrate-bearing materials are known locally under names which are supposed to denote the physical state and richness of quality. Caliche and Costra are the names mostly used, the former generally being the richer and purer, the latter being the poorer and the more impure. There is, however, no great consequence to be attached to these names at the present, as they are very often used interchangeably in different localities, but the name Caliche was originally applied to the kind of material containing very little insoluble matter and consisting essentially of nitrate of soda and common salt.

Caliche, however, may be considered to be the richer underburden, where costra is the poorer layer above it, it, in its turn, being usually overburdened by a layer of barren material.

The thickness of the deposits of both caliche and costra is variable, and at the same time both caliche and costra vary very much in physical structure, sometimes being hard and compact, sometimes soft and friable, and according to this nature can be sent to the works for refining with a nitrate content of 14 per cent and upwards. There are, however, qualities of costra which, even with contents of 22 and 25 per cent (and these might very well be called caliches), cannot be successfully treated by the processes in use to-day, because their compactness and imperviousness to water allows them to pass through the lixiviation process practically unaltered.

It is quite impossible to give a clearly defined description of what is costra and what is caliche, or to state any general rules as to which type of material should

or should not go into the works for refining. These factors are local and depend to a large extent upon the judgment of the manager of the works and the foreman and miners who are employed in removing the raw material from the grounds. For example, some types of stoney raw material with 10 per cent nitrate content may yield up all their nitrate to the attaching solutions, while other varieties of 15 per cent may only yield 4 per cent, or even nothing.

What is aimed at in the mining of nitrate-bearing raw materials is to get an average material as high in ley as possible, which will prove most amenable to the process of refining, yielding up to the solutions used for its lixiviation sufficiently high a proportion of its nitrate content while not causing too high a production of insoluble fines in the leaching tanks. This can only be attained by selection of material based on an extensive use of the personal equation.

It will be seen from this that so long as the present methods of refining are used, so long will the development of the mining of nitrate of soda on modern lines be delayed, and as a corollary so long will restrictions be placed upon the quantity of material which can be extracted from the grounds themselves.

The actual methods of mining of this raw material need not be gone into in detail in an article of this nature, but it might be sufficient to indicate that with the restrictions which have been referred to above there is very little possibility of being able to operate to advantage the mechanical methods of mining, which would so reduce costs of operation as has been found in other mining industries. It is even doubtful as to whether the modern methods of mining could ever be easily adopted in the Chilean fields in their entirety, assuming it were possible to treat an average grade of material of about 5 per cent. The main reason for this is the irregularity of the deposits, both as regards distribution and thickness.

The miners work on piecework, being paid a price agreed on for every cartload of suitable material passed to the works. The hand-selected material is loaded into carts holding from $2\frac{1}{4}$ to $2\frac{1}{2}$ short tons, the lumps weighing anything from 25 to 50 lb. It is kept as free from dust and barren overburden as possible, although a fair proportion of useless "smalls" is often brought in with the selected material. An average analysis of 22 per cent caliche used in the process might be taken as below:

Nitrate as nitrate of soda.....	22 per cent
Chloride as chloride of soda.....	30 per cent
Sulphate as sulphate of soda.....	4 per cent
Insoluble matter	54 per cent
100 per cent	

The nitrate is present as nitrate of soda, potash, lime, magnesia, though all of these bases are not necessarily always present.

Chlorine is also present allied with traces of these other bases, and sulphates of lime and magnesia are also present in varying quantities.

Method Employed in the Refining of Chile Saltpetre from the Raw Materials

In the most modern of the Chilean works the methods adopted to-day actually differ very little from those used thirty years ago. The principle on which the method is based depends upon the fact that sodium chloride is not sufficiently soluble in concentrated boiling solutions of nitrate of soda to contaminate the latter seriously when the solution is cooled in order to crystallize it. That is to say, that a saturated solution of salt, when warmed up and subsequently raised to the maximum boiling point in the presence of nitrate of

soda will take up the latter and deposit the salt to such a point that the nitrate of soda can be crystallized from the solution obtained by cooling, and the crystals obtained will be commercially free from sodium chloride contamination.

The raw material is passed through jaw crushers of the Blake-Marsden type, and the crushed material is lifted to the boiling tanks either by belt conveyor, bottom emptying car and hoist (electrical or hydraulic), or drawn up an inclined plane in a side tipping or bottom emptying car. Where a belt conveyor is used the actual distribution of the material to the tanks is done by means of the cars above referred to or, as in some cases, by belt distribution. The tanks, 32 ft. x 9 ft. x 8 ft., provided with false bottom 9 in. to 12 in. from the true bottom, three doors in the bottom for discharging ripio (refuse), steam coils for heating purposes and connections for transferring liquors and running off finished liquor and washes, are loaded with the crushed material. The size of crushing is varied, according to the hardness of the raw product, from 3 in. for the softest to $\frac{3}{4}$ in. for the hardest types.

The charge weighs anything from 60 to 70 tons. It is now leached in stages, usually four or five operations being necessary. The first is with the strongest liquor available, which is obtained from the tank immediately behind and whose origin will be seen from the description of the complete cycle, and this is carried out at the highest temperature to be obtained, the boiling being continued for a period of from two to three hours, according to the grade of material under treatment.

At the expiration of this period the boiling liquor, which is now strong enough to send to the crystallizing tanks, is slowly run off from a point about half way up the tank, the level of the liquor in the tank being maintained by feeding with the next strongest liquor from the tank behind. The "caldo," as it is called, is run off slowly for a period of from two to three hours, boiling and feeding being maintained all the time, and the flow is only stopped when the liquor has decreased in strength, due to the weaker feed not being able to be strengthened quickly enough in the boiling tank which is under review.

The feed liquor is intended to *replace* the caldo running off, but in actual practice it mixes with it and thus limits the efficiency of the operation. When the flow of caldo is stopped, "cut," the feeding liquor is stopped and the liquor in this tank is transferred by pump or by leveling action (or both) to the next tank forward, which contains fresh caliche, and the preparation of caldo proceeds anew from this fresh caliche. The tank which has now been boiled once is filled up with liquor from the tank behind it (this liquor is the result of the second boiling of this material in this tank) together with mother liquor from the crystallizing tanks and boiled for a further period during which the fresh caliche in the tank forward is being boiled for the first time with the liquor it has received from the tank under description, while the tanks further back are receiving their third, fourth and fifth treatment or washing. In this way the caliche is successively leached with four or five liquors in a cycle of operations, the first two leachings being at the boiling point, the third and fourth at lower temperatures, the final wash water being cold water. The whole operation takes eighteen to twenty hours per tank. The spent caliche, after draining, is discharged into wagons and deposited on the dump tips, the drained liquor being passed forward in the system in due course.

The strong liquor (caldo) is run into settling tanks, where it is clarified sometimes by "time" settling only,

sometimes with the aid of flour, dung, etc., and the clear liquor is decanted off into open troughs, through which it is conducted to the crystallizing tanks.

These crystallizing tanks are 15 ft. x 15 ft. x 2 ft. 6 in. x 3 ft., sloping to one side, and an outfit of these tanks is enough to allow of sufficient being filled each day and occupied for twelve to thirteen days, with a two days' supply in reserve. Thus a works filling ten tanks a day will require about 150 tanks for its equipment.

The cooling is done by exposure to atmosphere, and takes eight to eleven days, at the expiration of which the plugs, which are fitted in the bottom, are withdrawn, and the mother liquor drained off to open troughs below, which conduct it to the mother liquor stock tank. From here it is sent back to the system as above. The crystalline deposit in the tanks is equal to about 25-35 lbs. nitrate from 1 cu. ft. caldo, and for every 1 lb. nitrate deposited as crystal about 0.5 lb. returns to the system as mother liquor. The nitrate after draining contains 8 to 10 per cent liquor, and the crystals are heaped on the drying floors (into which some of the mother liquor drains and is lost), where the heaps are periodically raked over in order to expose more surface, and by atmospheric evaporation and draining over a period of a month the crystals are reduced to 2 to 3 per cent moisture contents, after which the lumps are broken down with wooden mallets and the nitrate filled into sacks, each holding about 200 lb., for entrainment to port.

In 1911 an English nitrate company began the construction of a new refining works (Oficina), which was designed for an output of 90,000 qtl. nitrate per month from material containing 25 per cent of nitrate of soda.

In this works the whole of the power for crushing and distribution of crushed material and for pumps was provided by a central electrical generating station containing two 200-hp. Diesel engines direct coupled to two three-phase alternators of Siemens Brothers. For the transmission of power to the wells and outlying places step-up transformers are used and the current transmitted on bare copper aerial lines.

The steam for process work was generated by oil-fuel-fired Lancashire boilers, of which five were installed (30 ft. x 7 ft. 8 in.).

The material was crushed in Blake-Marsden crushers, driven electrically, five of these said crushers being installed (24 in. x 18 in.).

The crushed material was elevated to the boiling-tank stage by belt conveyors and distributed by belt to the tanks for loading. There are eighteen boiling tanks, each 34 ft. x 7 ft. 6 in. x 8 ft. 6 in., provided with false bottoms 1 in. above true bottom, fitted with the necessary connections for transference of liquors and three ripio discharge doors for discharging the spent caliche. The latter is drawn to the dump tip side-tipping wagons drawn by petrol locomotives. The plant is equipped with 154 crystallizing tanks, each 18 ft. x 18 ft. x 3 ft. 6 in., sloping to 3 ft., the whole of these mounted on a substantial steel structure. The raw caliche is brought into the works by a light railway, 2-ft. 6-in. gage, 35-lb. rails spiked being used, drawn by locomotives constructed by North British Locomotive Company, Limited.

The mileage of railway in the grounds is $2\frac{1}{2}$ miles, and the loading stations are fed by carts and mules from the actual mining localities.

The water supply is derived from wells, as is usual in these districts, the power for pumping being supplied from the central station.

The plant is equipped with a very complete engineering workshop fully capable of dealing with all necessary

repairs for the efficient upkeep of so large a mechanical installation. It is also equipped with a small foundry for both brass and iron.

A description of one month's working will show what results are obtained in actual operation.

During twenty-nine days worked in one particular month there were brought in 12,484 cartloads of raw material.

Estimated weight of cartload 41 Spanish quintals (101.2 lb.), fifteen carts were employed in feeding the loading stations, each making about twenty-eight trips per day. Two locomotives and sixty-five side-tip wagons were used to transfer the material from the loading stations to the treatment plant.

The raw material averaged 21.89 per cent nitrate, and the total treated 499,544 Spanish quintals were divided into 350 charges (tank loads) of about 1430 qtl. each, and the yield showed, on the figures taken, an efficiency of 56.4 per cent. The figures are as follows:

Total caliche 499,544 qtls. at 21.89 per cent nitrate equals 109,356 qtls. nitrate	
produced 65,000 qtls. of 95 per cent nitrate equals 61,750 qtls. nitrate	
LOSSES	
In ripio 400,644 qtls. (dry weight, estimated) at 5.04%	20,192.45
In Borra 33,900 qtls. at 1745% nitrate.	5,915.55
Unaccounted for	21,492.00
	47,600.00

A recovery of 56.4 per cent of the nitrate contained was effected from raw material of about 22 per cent.

For each quintal of petroleum consumed 7.98 qtl. of nitrate were extracted, or in coal equivalent (taking the heat efficiency oil to coal as 18 to 12) 1 qtl. of coal produced 5.32 of nitrate.

With such a material as caliche this countercurrent system does not give most efficient results for a variety of reasons, chief among which are:

1. All liquors passing forward are saturated solutions of salt and nitrate at their temperature, and as they take up more nitrate with rise in temperature they deposit salt. When this salt is deposited around the lumps of caliche, it tends to act as a protective coating against the action of the succeeding liquors, which are themselves, as shown, saturated with salt.

2. The circulation in the tanks is very poor, for the tendency of the solid is to pack close during leaching, and hence the liquors passing through the charge will endeavor to take the line of least resistance. Under these circumstances, channels are liable to be formed in the solid, thus permitting certain of the contents of the tank to escape lixiviation altogether.

3. The solid on yielding up its nitrate to the attacking solutions loses the binding agent which has kept it in lump form, and the lumps fall apart in the form of sand, stones and clay, which were bound together in solid form by the crystals of soluble nitrate, etc.

The result of this is that it becomes exceedingly difficult to drain off the liquor from the solid, and thus every successive wash becomes a dilution of stronger liquor contained by the weaker following one, and as the final draining is equally poor, the net result is to dispose of the refuse containing not only undissolved nitrate, but a very high proportion of nitrate liquor containing.

During the course of the operations the space referred to between the true and the false bottoms becomes filled with the finest of the particles of the insoluble matter, which have found their way through the perforations in the false bottom. This is known as borra. This space was originally intended for the reception of this fine sandy matter, in order to keep the bulk of the charge free from it, but it is not sufficient nor can it be made sufficient to take the whole of the

fine matter produced during the disintegration of the raw material of leaching. Very slow passage of liquors during the leaching process tends to check this disintegration.

The more the material is leached the more of these fines will be produced, until eventually the whole of the raw material will be reduced to this fine state, when all the soluble matter has been dissolved.

When the design of this type of leaching tank was first introduced, the raw material contained quantities of insoluble matter varying between 10 and 25 per cent. Nowadays this percentage varies between 50 and 70, and the tanks have not been redesigned to cope with this additional quantity of insoluble matter. The fine sand and slime thus deposited remains wetted with the strongest liquor, and even after washing is discharged with about 18/24 per cent nitrate. That which cannot get to the bottom remains in the charge and causes it to retain more nitrate liquor than otherwise, thus making the spent charge wetter and richer and increasing the inefficiency of the process.

As a result of the operation of this method of lixiviation, only about 45 to 55 per cent of the nitrate contents of the raw material are extracted as crystal, and an average oficina's working on 20 per cent material might be tabulated as follows, taking a unit of 1000 tons:

<i>General Statement of Work Done in Nitrate Plant</i>		
	Tons	Per cent
Nitrate contents, original.	200	
Nitrate extracted	100	50
Nitrate in Ripio (refuse)	40	20
Nitrate in Borra (fines)	20	10
Nitrate unaccounted for.	40	20
	200	100

In some of the still more modern works, owing to very large quantities of raw material handled (1500 to 2000 long tons per day), material as low as 18 per cent average is being worked successfully, and this success is due to the attention to and development of the mechanical side of the work, thus diminishing cost of power and labor, and by the size of the installation diminishing the proportion of fixed overhead charges.

No attempt will be made to enter into the question of costs in this article, except to say that with the general high cost of mining and of labor and fuel on the lixiviation plant the costs of operation are high. This coupled with the low efficiency of the whole scheme leaves a comparatively open field for new processes and methods of operation.

The foregoing will have given sufficiently clear an outline of the methods in use to-day for the refining of nitrate of soda, in which about 170 plants are engaged, ranging in output from 1500 tons to 7500 tons per month each, these including old type of machinery and the most modern of installations.

New Projects

As stated previously, within the last four years or so a huge impetus has been given to the interest taken in the improvement of the methods of refining, and a large number of projects have been suggested for this purpose.

A number of these schemes are in process of being tried on the large scale, while laboratory work is still being pushed forward in this direction.

The writer will endeavor to give an outline of the direction in which the work is tending, and although it will not be possible to refer to the inventors and workers by name it will readily be realized how near is the solution of the problem which is being tackled by numbers of workers who are transferring their knowledge of chemical, mining and metallurgical proc-

esses and adapting them to the needs of the nitrate industry.

The problem has been attacked from many points of view, and for clearness of description these may be divided into two classes:

- (1) Auxiliary processes.
- (2) Complete processes.

Auxiliary Processes

Auxiliary processes may be subdivided into various classes, but as a general statement it may be said that an auxiliary process is one which has been designed to remove some of the salient difficulties of the old process and to assist the latter to obtain better and cheaper production.

The subdivision of auxiliary processes may perhaps best be made as follows:

- (1) Those which have as their basis the screening of the raw material before treatment in the main plant.

- (2) Those which have as their basis the further treatment of the refuse material from the main plant.

Although the methods pursued by these two classes of auxiliary processes differ according to the nature of the prime material they deal with, their objects are the same inasmuch as they aim at procuring a liquor which can be strengthened to the necessary point for crystallization by being passed over raw material in the old type of plant.

SCREENING (AUXILIARY) PROCESSES

Such processes are based on the idea that one of the main causes of the inefficiency of the present method of lixiviation is the presence of "fines" in the crushed raw material, these fines being present in such material partly due to the crushing, partly to the breaking down of the conglomerate during blasting in the mining and falling in of soft overburden, and also to the natural friability of some of the material and the breaking down of it during handling.

By screening in rotary screens after crushing, and using about 3/16 mesh, varied proportions of fines are separated out of the varied crushed materials, but it is generally assumed that a cleaner and better leaching can be obtained in the old type of plant when it is fed with a screened product. No doubt this is true to some extent, but, as the leaching itself causes the production of fines in the tanks, the good results from the above will depend to a large extent on the nature of the raw material being treated in the original plant and will necessarily be limited by this.

From this point the methods adopted in the auxiliary processes for the treatment of the fines may be divided into three classes, depending as to whether

- (1) Grinding and vacuum filtration,
- (2) Pressure filtration, or
- (3) Classification and partial filtration

is adopted as the basis of the method of treatment.

In the first of these methods of treatment the fines (3.16 mesh) are ground in a ball mill with weak nitrate solution until a pulp is obtained of sufficient fineness (100 mesh) to permit it to be treated in a vacuum filter. The pulp is then heated up in order to cause solution of the nitrate contained in the solid and the hot pulp is filtered through a vacuum filter.

For this purpose the well-known and well-tried vacuum filters are used. The liquor which is withdrawn from the filter is sent to the main plant to be used as a feed liquor in the main operation, and the cakes are washed, first with a weak nitrate solution, and subsequently with a brine wash (the recovered washes being used in the cycle for the next treatment), the finished cakes being discharged practically barren of nitrate.

In the second of these methods the fines, without

grinding, are heated up with weak nitrate solution and filtered in pressure filters. The recovered liquor is sent as before to the main plant, the cakes being washed with weak nitrate solution, and finally with brine and discharged.

In the third the fines are treated with weak nitrate solution to complete the disintegration of the raw material, and the pulp obtained is classified in order to separate the slimes and fine sand (80 mesh). The remaining sands and stones are washed in a counter current system, being discharged with practically no nitrate content at all, while the slimes and fine sands are separated from the liquors obtained by vacuum or pressure filtration. The amount of solid filtered by this method is only about 20 per cent of the total insolubles and no grinding is necessary.

Whereas it is claimed in all three methods that complete lixiviation is procured and the refuse discharged with no nitrate contents at all, it is probable that costs of operation will be higher in the first and second methods than in the third method.

All these methods, however, leave this much to be desired. The proportion of fines which can be treated in the auxiliary plant is limited by the amount and ley of the cleaned coarse material sent to the main plant, because the auxiliary processes do not aim at the production of a directly crystallizable liquor, but only at one of such strength as can be sent to the main plant as a feed liquor.

If, as an example, 80 per cent of the nitrate in the raw material were contained in the fines the remaining 20 per cent in the coarse would not be sufficient to strengthen the liquors obtained from the auxiliary process unless such a process produced a correspondingly strong liquor. Of course, the removal of only a portion of the fines by screening, limits immediately the utility of the auxiliary processes by reducing the advantage gained in the main plant of treating cleaned coarse material.

The strength of liquor that can be obtained by the auxiliary treatment process is limited by many circumstances.

In the first case high temperature pulps (meaning high nitrate content of liquors) are not easy to handle, because of the tendency to rapid crystallization on the part of such liquors by cooling.

Secondly, the vacuum filter imposes a limit on the temperature of the liquor which can be passed through it and the pressure filter must be closely jacketed.

And lastly, if the pulp, after filtration and before washing, contains 30 per cent liquor content, which is quite likely to do by vacuum or pressure filter, this liquor will hold as much or more nitrate in the cake as the dry fines had in them before treatment. This means that the actual extraction of nitrate from the fines will be done by the first wash, which must in that case be an absolute displacement of the strong liquor, as mixing during the wash would reduce the strength.

Assuming fines of 14 per cent nitrate content to be treated for production of a liquor of 750 gm. nitrate per liter (say, 50 per cent nitrate by weight):

100 lb. fines equal say 14 lb. nitrate.

11 " salt,
75 " insolubles.

i.e., 86 lb. cake forming insolubles.

Liquor content of cake in or on filter before washing equals, say 30 per cent.

$$\begin{array}{rcl} \text{Then total weight of cake} & = & \frac{86}{70} \times 100 = 122.8 \text{ lb.} \\ \text{of which 86 lb. is insoluble} & & \frac{86.0}{36.8} \end{array}$$

This liquor being 50 per cent by weight of nitrate, there will remain in the cake 18.4 lb. nitrate. This excess over the 14 lb. nitrate originally present in the 100 lb. fines is taken from the extracting liquors. The wash must be a complete displacement wash or the 18.4 lb. nitrate will not be regained as liquor of 50 per cent strength.

Although there are limitations to the auxiliary processes of this kind themselves and to the use of them in connection with the main plant, they are being applied to the different plants at present in their limited capacity with very beneficial results.

The second class of auxiliary processes depends on the treatment of the refuse from the main plant by any of the three methods described above.

The whole of the refuse is ground in tube mills and either filtered or classified and partially filtered, with the result that the nitrate which would otherwise be discharged with the refuse on the dump tip is regained from it in the form of liquor which is used as a feed liquor in the main plant.

It will be obvious that the methods used in these auxiliary processes will be capable of application as a complete process, that is, one which will treat the whole of the raw material, if the liquors produced by them can be brought up to proper crystallizing strength by an efficient system of concentration and evaporation in the absence of being able to produce such liquors direct. It is claimed, however, that with the use of pressure filters such liquors can be easily obtained and the large-scale operations will prove later at what cost and what is the lowest ley of material which can be so treated.

An efficient process of evaporation would, however, make these auxiliary processes into complete ones and confer on them the ability to reduce the ley of the raw material to the minimum (thus reducing cost of mining considerably) by reducing the strength of the ultimate strength of solutions aimed at compatible with the costs of evaporation. In such an evaporation plant not only must the cost of evaporation be within commercial limits, but the design must be such as will efficiently cope with the greatest problem set before it in the handling of liquors which are below the saturation point for nitrate, viz., it must efficiently deal with the quantities of salt thrown out of solution during the evaporation. In working to the complete extraction of the nitrate contents of raw nitrate-bearing materials, not only will all the nitrate be dissolved, but also larger quantities of salt than heretofore, as well as the other soluble salts which may be present.

In concentrating the liquors obtained up to the necessary point to obtain crystallization of the nitrate contained, not only must the plant be capable of dealing with the salt thrown out of solution, and disposing of it free from nitrate, but it must be capable of producing so little mother liquor as to render easy the problem of disposing of the more soluble salts, such as calcium and magnesium chlorides and nitrates which would otherwise accumulate to the detriment of the process. Such a form of evaporator is now before the nitrate producers, and a plant capable of producing 2500 long tons per month is now being constructed in this country for delivery to Chile. The principles of this evaporation plant have been worked out in England on an experimental plant capable of producing 500 tons per month during a period extending over two and a half years, and in its present form it is confidently expected to reproduce the excellent results obtained in the trials and demonstrations carried out on the smaller scale.

In this type of plant, known as the Gibbs nitrate

evaporator, the above desiderata have been constantly borne in mind in addition to which continuity of operation has been sought for and arrived at.

The plant has been designed to act as a multiple effect evaporator, in the lower temperature effects of which part of the desalting is carried out, and in the final high temperature effect the temperature reached is so high as to practically complete the desalting. The desalted liquor is then crystallized by further evaporation in vacuum and the nitrate is regained as a continuous operation.

Special precautions have been incorporated in the design so as to prevent as much as possible incrustation of salts on the heating tubes, and also to provide for the settlement and removal of the deposited salt without interfering with the continuity of the operation.

The salt from each stage of the operation is washed and disposed of, and in the case of the salt separated at the high temperature it is collected and washed practically without loss of temperature, thereby preventing crystallization (and indirect loss) of nitrate with it. Wash liquors are returned to the evaporation system.

Complete Processes

With the introduction of an ultimate system of evaporation such as is outlined above, considerable assistance may be rendered to the development of what has been described as the auxiliary processes. In conjunction with such a system they become complete processes, and no doubt as the costs of the operations such as are used by these auxiliary methods are properly elucidated and compared the cheapest and most efficient of them will be gradually adopted as standard.

The inventors of the evaporation plant referred to at present place their faith in the lixiviation process which, through classification and partial filtration, carried out at a tepid condition of temperature only, arrives at a complete extraction of the soluble contents of the raw material producing a liquor of about 30 per cent nitrate content by weight. This liquor is produced by the lixiviation of the raw material with water as the starting point and no return of liquors from the evaporation section is made.

The lixiviation section has under these circumstances the best possible chance of yielding the best results.

The evaporation section is quite separate from the lixiviation section, and as it only produces sufficient mother liquor to enable the crystal nitrate to be removed from the plant and dried in hydroextractors, this mother liquor is able to retain the more soluble salts together with the remaining sodium chloride, due to incomplete desalting. This mother liquor can be discharged from the cycle for purification periodically and sent back to the evaporation plant practically only carrying nitrate of soda. With such a complete process the cost of operation will be made up of cost of mining, cost of lixiviation, cost of evaporation, and these three factors can be adjusted to each type of material, depending on its original nitrate content and the strength of solution it is best to work for.

It is on these lines that the development of the refining of Chile saltpeter is taking place, and the ground is well prepared for such development.

Capital has interested itself in the newer ideas and objections to the introduction of completely new methods have died away or are slowly dying.

Rivalry between the workers on the development schemes on a healthy scale is assisting rather than hindering the progress, and from all points of view it must be agreed that a very bright future is assured to the Chilean industry from the results which will follow:

1. Increase in estimated life of properties.
2. Decrease in working costs.
3. Decrease in costs of newer installations.
4. Reduction of labor difficulties.
5. Increased control over methods of refining and mining.
6. Attraction of new capital and new blood to the industry due to its new activity and life.

The Analysis of Light Oils

Contribution from the Haysmeyer Chemical Laboratory,
Columbia University No. 293.

By Gustav Egloff

The rapid, safe and accurate analysis of light oils resulting from the thermal decomposition of coal, shale or petroleum oil for their benzene, toluene and xylene content is of considerable industrial importance. In this communication a method is described which embodies the essentials of safety from fire, reasonable rapidity and a relatively high degree of accuracy. The still used consists essentially of an eight-foot column of iron pipe, of foot lengths of iron pipe, with a reflux tube running below the distilling liquid in a copper flask of four liters capacity. The still was tested experimentally with varying percentage composition mixtures of benzene, toluene and xylenes. The concentration of benzene studied ranged between 2.0 to 80 per cent; the toluene between 3.0 and 90 per cent, and 6 to 58 per cent for the xylene concentration.

In addition to the determination of the accuracy of the still, an outline of the washing of a light oil free of olefins, neutralizing, steam distillation, drying and percentage composition of paraffins, benzene, toluene and xylenes (or solvent naphtha) present will be given.

DESCRIPTION OF STILL

a. The column, eight feet in length, is made up of six sections of three-quarter inch pipe, one foot each in length, another eighteen inches in length, and one section of one and one-half inch pipe, six inches long. Each section is connected by means of a sleeve, and the last section with a three-quarter, one and one-half inch reducer. Between adjacent sections there is a 30-mesh iron gauze used as a diaphragm to support an eight-inch column of two-inch glass rods of one-eighth-inch diameter.

b. The reflux part of the column is made from one-quarter-inch pipe, and is six and one-half feet in length. It taps into the column six inches from the top, extends downward on the outside, and enters the column a

FIG. 1—STILL CONSTRUCTION

foot from the bottom at the top of the one and one-half inch diameter section. It extends to within one inch of the bottom of the copper flask when the whole apparatus is connected. Three one-quarter inch elbows and tees, one one-quarter inch reducer union are used to make the fittings. Three one-quarter inch nipples tap into the three-quarter inch pipe, as shown in the drawing.

c. Attached to the top of the column is a tee which allows a thermometer to be inserted through one opening, and a three-quarter inch pipe in a horizontal direction, nine inches in length. At the end of this horizontal section is a reducing elbow of three-quarter one-half inch. A half inch pipe extends downward from this reducer, to a twenty-four inch condenser.

d. The connection between the column and the copper flask is made by means of a one and one-half inch Dart union, one section of which is connected to the bottom of the column, and the other to the neck of the flask.

e. The flask is made of copper with a capacity of 4000 c. c. It has a flat bottom of six inches diameter. To the neck, a one-one-half inch Dart union is brazed. The flask may be varied in size dependent upon the quantity of oil desired.

f. In order that the distillation may proceed evenly, it is best to surround the burners with a three-way asbestos screen to prevent drafts. It has also been found advisable to set the column in a box with a hinged door, which may be opened and shut at will. This door is closed at higher temperature distillations. This precaution is not necessary if the distillation is conducted in a room, which is free from drafts.

g. The manipulation of distillation is quite simple, although care must be exercised when first applying heat to the flask. If too much heat is applied the system floods. The reflux is not sufficient to carry off the column of liquid lifted by the supporting vapors. One can note the process of distillation by the temperature of the various sections of iron pipe, by simply touching. The rate of distillation is exceedingly important, for without this control a good separation is impossible. The work of Brown² has clearly emphasized the fact that the rate of distillation influences greatly the separation of mixtures. The data in Table 1 show experimentally the wide differences resulting, when thirty, sixty or one-hundred and twenty drops per minute are used, in distilling a benzene and toluene mixture.

TABLE 1
Mixture of Benzene and Toluene

Temperature Range	Number of Drops of Distillate per Minute		
	30	60	120
Percentage Weight of Distillate			
80.2-83.2	0.8	0.6	0.6
83.2-86.2	29.6	21.8	10.8
86.2-89.2	9.8	14.3	20.2
89.2-92.3	7.6	7.8	12.6
92.3-95.4	3.8	5.0	7.0
95.4-98.5	3.0	4.7	5.4
98.5-101.6	2.8	4.0	5.0
101.6-104.6	2.0	3.6	5.0
104.6-107.6	4.3	5.2	5.6
107.6-110.6	6.2	7.3	9.2
110.6-116.6	11.6	9.8	11.1
Pure toluene by difference	19.5	15.9	7.6*
	100.0	100.0	100.0

*Temperature barely reached 110.6, residue not quite pure toluene.

In the present work two drops per second were found to be satisfactory. The two drops per second were checked by means of a metronome and stop watch. The end of the condenser was cut off square, so as to obviate constrictions, which would give a different size drop, hence affecting the rate of distillation.

Two thousand c. c. of mixtures of benzene, toluene and xylenes were distilled in each experiment. The

¹Shown in Fig. 1.

²Trans. Chem. Soc. 37, 49, 1880.
³Young's "Fractional Distillation."

average time of distillation was four hours and thirty minutes, or approximately seven and one-half c. c. per minute. The concentrations used for benzene ranged between 2.0 and 80 per cent; toluene, 3.0 and 90 per cent, and for the xylenes, 6 to 53 per cent.

The cuts were made at 95 deg. C. for benzene; and 95 deg. to 125 deg. C. for toluene.

The volumes of benzene, toluene and xylene were measured by means of calibrated measuring cylinders of 500 c. c. capacity. The smaller volumes were measured by means of a standardized burette of 100 c. c. capacity.

h. The purity of the benzene, toluene and xylenes used was of a relatively high order. They were water-white in color, and gave no color upon treatment with c. p. 1.84 specific gravity sulphuric acid. The benzene gave no test for thiophene by means of the indophene reaction. The distillation of the benzene, toluene and xylenes was made in a standard 200 c. c. Engler flask (Table II.). The specific gravity was taken by means of a Westphal balance at 15.5 deg. C.

TABLE II
Engler Distillation of Benzene, Toluene and Xylenes

Per cent by vol.	Sp.Gr.0.881	Sp.Gr.0.871	Sp.Gr.0.869
First drop	79.5° C	109.1° C	137.1° C
2.5 per cent.....	80.1° C	109.8° C	138.2° C
5.0 per cent.....	80.3° C	110.0° C	138.3° C
95.0 per cent.....	80.7° C	110.4° C	139.4° C
97.5 per cent.....	80.9° C	110.5° C	139.6° C
Dry point	81.3° C	110.7° C	140.0° C
Distillation range.	1.8° C	1.6° C	2.9° C

i. The advantages of the proposed still may be summed up as follows:

1. It has a relatively high degree of accuracy in determining the percentage composition of aromatic hydrocarbons present in a light oil.

2. It allows of large quantities of liquid to be distilled.

3. The apparatus is not liable to break, is inexpensive and makes the distillation of inflammable liquids relatively safe from fire hazards.

4. The distillation losses are small, due to one fractionation only being necessary and very small amount of residual liquid remaining in the fractionation column.

5. It is simple to operate and requires little attention after being regulated. One individual can operate four stills at one time.

6. It contains in essential the advantages outlined by Young.⁴

"Fractional Distillation," 1903, p. 176-177.

Table III tabulates the analytical results of various concentrations of benzene, toluene and xylene. The

data speak for themselves, showing the relatively high order of analytical accuracy of the type of still used in the above set of experiments. It must be recognized that the benzene recovered in the cut to 95 deg. C. is not pure benzene, but contains a small per cent of toluene, as likewise the toluene cut of 95 deg. to 125 deg. C. contains a small per cent of benzene and xylene. But the percentage of the constituent contaminating the fraction from the viewpoint of absolutely pure substance balance each other, so that for analytical purposes of industrial significance, the cuts to 95 deg. C. (benzene), 95 deg. to 125 deg. C. (toluene), may well be taken as the actual amounts of benzene and toluene present in the starting mixture.

In actual distillation the benzene comes over mainly, close to its boiling point of 80.2 deg. C. The thermometer climbs rapidly, with little liquid coming over to the boiling point of toluene of 110.6 deg. C. Likewise for the amount coming over between the boiling point of toluene and the xylenes of 137 deg. to 140 deg. C. To separate the mixture into pure benzene, toluene and xylene a number of redistillations would be necessary for their separation.

The analytical data in Tables IV, V, and VI represent mixtures of commercial concentrations from by-product coke-oven plants and the Pintsch gas process and are known as primary, secondary, and hydrocarbon oil. To compare the present single distillation method in an 8-ft. column, a standard Hempel column (shown in Fig. 2) was used with a flask of 500 c.c. capacity. The great advantages of the Hempel apparatus are efficiency, simplicity and ease of manipulation. But,

FIG. 2—HEMPEL COLUMN

three distillations are necessary when a Hempel column is used, as has already been shown in another communication.⁶ To indicate the temperature range of the distillation of the fractions, a standard Engler flask of 200 c.c. capacity was used. The distillation was made in each case for each fraction using 100 c.c. samples of the benzene cut, to 95 deg. C., toluene cut 95 deg. to 125 deg. C., and the residue. The Engler distillation of the cuts gives important information as to the efficiency of the fractionation. The temperature range over which the cuts distil is given comparatively for the 8-ft. and Hempel column, in the following table:

	Temperature Range, Benzene Cut		Temperature Range, Toluene Cut		Temperature Range, Residue	
	8' Col., Deg. C.	Hempel, Deg. C.	8' Col., Deg. C.	Hempel, Deg. C.	8' Col., Deg. C.	Hempel, Deg. C.
Primary oil	8.1	12.0	20.2	22.0	6.1	9.0
Secondary oil	21.0	23.2	33.6	31.6	6.1	9.1
Hydrocarbon oil	11.4	15.6	31.4	33.4	7.0	9.3
Light oil from cracked petroleum	56.5	60.5	31.0	31.5	110.0	115.5

The temperature range at which the benzene, toluene and xylene cuts distil indicates quite clearly that a considerably better fractionation of the starting oil has been accomplished in one distillation with the 8-ft. column in comparison to three fractionations with the Hempel column.

The data in Table VII express the analytical results of the percentage composition of the benzene, toluene

⁶Rittman, Twomey and Egloff, This Journal, V. 13, p. 682, 1915.

and xylene in a light oil resulting from the thermal decomposition of a petroleum oil. The percentages of the aromatics present were calculated by means which are given in the following section. In analyzing the exceedingly complex mixture of a cracked petroleum light oil, where the olefin, paraffin, naphthene and aromatic hydrocarbons present, have similar boiling points, it is practically impossible to separate them by fractionation; hence the analytical results of the aromatic hydrocarbons present are very likely not accurate to closer than 5 per cent.

Method of Analysis for Light Oil SPECIFIC GRAVITY

The specific gravity of the oil and of the distillates is determined by means of a Westphal balance at 15.5 deg. C.

OLEFINS

A sample of 2000 c.c. of the original oil is measured accurately in a graduated cylinder and transferred to a bell jar of 3000 c.c. to 4000 c.c. capacity, with a glass stop cock cemented in the lower part. Setting within the bell jar is a 1½-in. diameter lead coil, for water circulation. A lead paddle wheel is utilized for stirring which can be run by a system of gearing from a small motor. A lead plate covers the bell jar through which suitable holes allow of the stirring device, cooling coil, and place for a 500 c.c. separatory funnel.

While the cooling water circulates through the lead coil and stirring goes on, 200 c.c. of 95 per cent C. P. sulphuric acid is run into the light oil at the rate of one drop per second or approximately 3¾ c.c. per minute. The deolefinizing of the 2000 c.c. sample requires one hour and twenty minutes or so.

After the addition of the 200 c.c. of 95 per cent sulphuric acid the system was allowed to stand for one-half hour, so as to give time for the two liquid layer systems to reach equilibrium. The acid layer which contains sulphonic acids of the olefin series hydrocarbons, and other complexes, is separated. After the removal of the acid sludge, the acid dissolved in the light oil is neutralized with a 6 per cent solution of caustic soda. The caustic soda solution and oil are stirred for fifteen minutes and allowed to stand for thirty minutes. The caustic soda sludge is then drawn off.

STEAM DISTILLATION

All the oil residue so obtained, freed from olefins as above, is now placed in a copper container of four liters capacity and distilled with live steam until the temperature reaches 180 deg. C., at which point practically all the light oil has distilled off. The condensed water is separated by means of a separatory funnel and the light oil thoroughly dried with fused calcium chloride. After drying, the oil is filtered free of calcium chloride. The dried oil is distilled by the method already given.

The distillate collected up to 95 deg. C., is the benzene fraction, that collected from 95 deg. C. to 125 deg. C. is the toluene fraction, and that collected from 125 deg. C. to 165 deg. C. is the solvent naphtha fraction. The volume of each of these fractions is carefully determined and the specific gravity of each fraction is taken at 15.5 deg. C. by means of a Westphal balance.

If the specific gravity of the benzene fraction is not below 0.880, that of the toluene fraction not below 0.871, and that of the solvent naphtha fraction not below 0.870, these fractions contain no paraffins, and their respective volumes represent the amounts of pure benzene, pure toluene and pure solvent naphtha in the 2000 c.c. of oil originally taken. If the specific gravities of the fractions are below the figures given, then paraffins are present and corresponding deduction must therefore be made.

PARAFFINS

A method of calculating the percentage of paraffins present in the benzene and toluene cuts is based upon the wide difference between the specific gravity of the paraffins and aromatics. The average specific gravity of the paraffin hydrocarbons to 95 deg. C. is 0.720 while the value for benzene is 0.881. For toluene the value is equal to 0.871 while the paraffins in this cut of 95 deg. C. to 125 deg. C. are equal to 0.730. The following numerical example will make the process of calculation clear.

Cut to 95 Deg. C.	
Specific gravity, paraffin hydrocarbons.....	0.720
Specific gravity, benzene.....	0.881
Specific gravity of cut to 95 deg. C.....	0.841
Subtract 0.720 deg. from 0.841 deg.....	12
Subtract 0.720 deg. from 0.881 deg.....	16

12
Assume that 75 c.c. collects in cut to 95 deg. C. —
16

× 75 c.c. = 56.2 c.c.'s benzene in cut to 95 deg. C.

Since 2000 c.c. was used, the percentage of benzene in the sample is 2.8.

The quantity of paraffins contained in the several distillates is experimentally determined in the following way (which gives fair values of the percentage present).

Ten cubic centimeters (10 c.c.) of distillate are mixed with 25 c.c. of a mixture of two parts by volume of sulphuric acid (specific gravity 1.84) and one part by volume of 20 per cent oleum (fuming sulphuric acid). The mixture is thoroughly agitated in a 50-c.c. graduated cylinder with glass stopper and then allowed to settle.

Any paraffins present remain undissolved and their volume so determined divided by ten and multiplied by the total number of cubic centimeters in the particular distillate being examined gives the total volume of paraffins contained in said distillate. This quantity deducted from the total volume of distillate gives the net volume of distillate.

The percentage of benzene and toluene corrected for the paraffins if present in the light oil, are calculated as follows:

$$\frac{\text{Percentage of hydrocarbon}}{\frac{\text{Corrected volume of fraction}}{2000}} \times 100.$$

SPECIFICATIONS FOR BENZENE AND TOLUENE

In the use of benzene and toluene for the formation of phenol or picric acid and trinitrotoluene fairly rigid specifications are demanded as to their specific gravity, boiling points, color and sulphuric acid test. The following outline covers specifications which allow of their use for the above-named compounds, in the usual industrial operation.

Appearance:

(a) The toluene and benzene shall be water white in color and clear.

Specific Gravity:

(b) The specific gravity of toluene shall be between 0.869 and 0.872 at 15.5-15.5 deg. C.

The specific gravity of benzene shall be between 0.879 and 0.884 at 15.5-15.5 deg. C.

Boiling Point:

(c) The toluene shall boil within plus or minus 1 deg. C. of its boiling point of 110.0 deg. C. Of a 100 c.c. sample 90 per cent shall distil within 0.5 deg. C.; 95 per cent within 1.0 deg. C. The first drop shall not distil below 109.0 deg. C. and dry at 111.0 deg. C.

The benzene shall boil within plus or minus 1 deg. C. of its boiling point of 80.2 deg. C.; 95 per cent of its volume shall distil within 1.1 deg. C.

Sulphuric Acid Test:

(a) The toluene and benzene shall not impart more than a very faint straw color to sulphuric acid of 95 per cent concentration.

Method of Testing:

Specific Gravity—

(b) Determine by means of a Westphal balance, correct the result so as to compare the toluene at 15.5 deg. C. with water; also at 15.5 deg. C.

Boiling Point:

(c) Employ a 200-c.c. distillation flask with outlet tube $1\frac{3}{4}$ above the bulb. Connect to a Liebig condenser about 24 in. long over-all with a straight condenser tube unobstructed at the end. Place 100 c.c. of the sample of the toluene or benzene in the flask and adjust a thermometer graduated in tenths of a degree C. so that the top of the bulb is on a level with the side tube. Apply heat to a small area over the bottom of the flask and conduct the distillation in such a manner that the distillate passes over as quickly as possible in distinct drops. Collect distillate in a 100 c.c. graduated measure, read the temperatures at which (a) first drop of distillate falls from the end of condenser; (b) 2.5 c.c.; (c) 5 c.c.; (d) 9.5 c.c.; (e) 97.5 c.c. have collected. Finally record the temperature when the flask just becomes dry. Correct the readings for exposed mercury column and for barometric pressure. Allow 0.043 deg. C. per m.m. difference from normal atmosphere.

Sulphuric Acid Test:

(d) Shake for five minutes 50 c.c. toluene or benzene and 5 c.c. of 95 per cent sulphuric acid in a cylinder fitted with ground glass stopper. After settling, the color of the acid layer is observed. It should not be darker than pale, straw yellow.

The Determination of Zinc

By J. H. Hastings

Both the American Chemical Society¹ and the Australian Institute of Mining Engineers² have had committees working on the subject of a standard method for the determination of zinc in ores and each have recommended for adoption a different method than the one in common use by chemists and assayers in the West and to a somewhat more limited extent in the East. The former recommended Waring's method, slightly modified, and the latter the titration in an alkaline solution.

We are indebted to A. H. Low³ for the general scheme of the titration of zinc in an acid solution as commonly used. I shall outline his method as modified for works' use, and for simplicity take for example an ore that is decomposed by nitric acid and potassium chlorate.

Weigh 0.5 gram into No. 2 (250 cc. capacity) beaker; add 0.5 gram potassium chlorate, cover with watch glass and add 10 cc. HNO₃. Wait until first violent action ceases, a minute or two, place on hot plate or sand bath, and run to dryness slowly; have the beaker just hot enough so that the mass will froth up about one inch. When dry, tip up cover and catch drop against the side of beaker. Remove from heat. It is no advantage to leave the beaker on plate after the contents are dry, but rather is to be avoided, and take care not to allow the contents to fuse. This last precaution is taken to facilitate the later solution of the zinc. Cool, add 7 grams ammonium chloride, 20 cc. ammonia, 5 cc. bromine water (the last for ores containing little or no manganese), and fill the beaker one-half full with hot water. Boil from four to six minutes at a moderate

heat. For ores containing much manganese, add 15 cc. bromine water at first and 10 cc. more after contents have boiled one or two minutes, still boiling the total time of from four to six minutes. Remove, filter through a No. 3 Munktell or similar filter paper into a No. 3 (350 cc. capacity) beaker, washing off cover and down sides of beaker with hot water. In filtering pour on the side of filter paper to avoid splattering and have the stem of the funnel against the filtrate beaker, so that the liquid will run down the side and not just drop into the liquid already in the beaker and spatter out, causing loss of zinc solution. Wash out beaker and wash precipitate ten to twelve times with the wash solution made by dissolving 100 grams ammonium chloride in hot water, adding 50 cc. ammonia and making up to one liter.

Add a couple drops of saturated solution of methyl orange solution, neutralize with hydrochloric acid and add 5 cc. excess. The volume should now be 200 cc., and with some practice the washings can be gauged so that this will be the case.

Heat to boiling, add 50 cc. saturated H₂S water, and titrate slowly, stirring briskly, using 5 per cent solution uranium nitrate for indicator. It is best to work with a reserve portion, say 20 cc., and add portions of it until the final end point is reached.

Oxidized ores may be treated with 10 cc. hydrochloric acid, evaporated to a few cc., but not far enough for any part of the bottom of the beaker to be dry, as this condition may result in loss of zinc through volatilization. The acid should not boil.

To standardize, weigh out the same amount of zinc as the ore contains, so that the titration will be within 10 cc. of the number cc. the titration of the ore will require. The metallic zinc used should be specified for standardizing and marked with the analysis of the manufacturer.

GENERAL DISCUSSION

Decomposition: The safest manner to decompose sulphide zinc ore is with the 5 gram potassium chlorate and 10 cc. nitric acid. This procedure results in partial precipitation of the manganese and makes a good body from which the zinc can subsequently be extracted without any trouble. The precipitation of the iron and manganese and partial extraction of the zinc in the manner indicated is quite efficient, but the zinc remaining in the iron precipitate must be extracted. This zinc is more or less insoluble in a solution of ammonium chloride, weaker than 10 per cent.

As to redissolving this precipitate and reprecipitating, much less of the zinc will be carried down the second time, and possibly with a third precipitation the zinc could be entirely extracted, at least with the limitations of the analysis. I have heard of six such precipitations being made. The chance for loss is apparent. One chemist told me that he had made three such precipitations in a determination on an ore which he thought contained manganese and he was laboring under the delusion that this procedure would separate the manganese from the zinc, when, as a matter of fact, it hinders that separation to redissolve this precipitate, as some manganese has already been precipitated by the chlorate and nitric acid. At any rate it was quite evident that the ore in question contained no manganese, as this metal, if in appreciable quantity (enough to effect the zinc determination), is shown by the brownish color of the mass on the first evaporation and the residue on this ore was pure white.

Another method of extracting the zinc from the iron precipitate is to add 50 c.c. alkaline, 10 per cent ammonium chloride solution and boil. It is a hard matter to thoroughly extract the zinc in this manner, as some of the zinc is apt to reprecipitate as the boiling continues and there is a state of equilibrium reached when

¹J. Am. Chemical Soc. 1907-29-265.

²Proceedings—1913-10.

³Methods of ore analysis, 1913. Chp. XXX, p. 284.

while some zinc is dissolving some zinc is reprecipitating, and besides if all the zinc is dissolved the next procedure in this modification is washing four to six times with hot water, in which case some of the zinc is likely to reprecipitate on the filter upon dilution with water. This is an explanation, I believe, of why some results are low on ore running from 40 to 50 per cent zinc and 8 to 10 per cent iron.

The process of washing is very important, and it is unfortunate that analysts are, as a rule, untrained in this phase of chemical manipulation. There are certain ores on which it is difficult to extract the zinc from the iron precipitate. For instance, an ore running 16 per cent zinc and 30 per cent iron, or one containing 43 per cent zinc and 15 per cent iron, I have found difficult, and to require twelve washings instead of ten.

To wash the precipitation, have the extraction solution nearly boiling. On the first washing, start at the rim of the filter paper and wash around a couple of times, descending to the point of the filter. On subsequent washings wash down the point of the filter, stirring the iron precipitate well, say, the lower inch of the filter; then, still washing, circle around the filter paper with wash stream, gradually working up to the rim of the paper, and then around down to the vortex again, giving the iron precipitate a final churn with the stream. This leaves about an inch of liquid, measured up the side of the paper, in the filter. Keep blowing just hard enough so that the stream will not break the filter paper, but blow as hard as the filter paper will stand. The volume of the filtrate will be about 200 to 225 c.c. This makes about 12 to 13 c.c. for each washing. Several small washings are more effective than a few large ones.⁴

Neutralizing should be done carefully and exactly 5 c.c. hydrochloric acid added in excess as the uranium ferrocyanide is slightly soluble in hydrochloric acid, depending on the strength.⁵

The beaker is covered, set on a warm place until ready to titrate, then brought to a boil and the 50 c.c. hydrogen sulphide water added. It is not necessary to boil out the bromine, but it does no harm to do so.

The titration is perhaps the most difficult part of the whole determination to master. In the first place, provided the solution has been standardized correctly, it is not likely for one to get low results through faulty titration. But, on the other hand, it is a simple matter to be too high. We will assume that the standard solution is correct; then for a novice to hope to be correct in his results he must bear in mind several things. One of the first is to have a saturated hydrogen sulphide solution in an amber-colored stoppered bottle.

Have this solution strong enough so that you cannot stand more than one strong sniff of it. Add 50 c.c. to the zinc solution, stir well for several seconds. Pour off, say, 20 c.c. Run in the standard solution slowly, stirring vigorously, until after testing from time to time the end point is reached. The zinc solution generally turns milky at this stage, but it takes some experience to be able to note this change. Then add half the 20 c.c. and again titrate to an end point, repeat with half the remaining 10 c.c., then run very carefully until the end point is again reached and put in final 5 c.c., and finish the titration. When the last 5 c.c. are emptied into the main beaker the solution is poured back into the first beaker. Repeat to rinse the reserve beaker. The proper way to stir the solution is to stir once around about half way down between the center and sides of the beaker; then reverse and

stir back to the starting place. Repeat this operation about three times, then stir from one side of the beaker to the other through the center, repeating this procedure three times. This is the general idea of thoroughly churning up the liquid with little danger of splashing any out of the beaker. I might say that the stirring cannot be done effectively with a glass rod, but it is better to use a hard rubber rod with a soft rubber tip, so as to avoid breaking the beaker.

The end point is the first faint change to a reddish color. A "fake end" point sometimes shows up, especially if the titration is carried on rapidly. This sometimes shows up as early as 10 c.c. before the true end point, but can be detected by the fact that it does not get deeper in color if more ferrocyanide solution is added.

A turning green of the solution can be accounted for either by the decomposition of the potassium ferrocyanide through the presence of an oxidizing agent, and in this case the hydrogen sulphide water is not strong enough to do its part and should be strengthened by bubbling more gas through it. The other cause for a green color is the presence of iron, which has gotten in the solution through contamination. This sometimes can be traced to the hydrogen sulphide water, too, as often the wash water for the gas generator bubbles over into the receiving bottle or iron may run through or over the edge of the filter paper in filtering, and thus gets into the filtrate.

Too high results are more apt to be obtained on high titrations over 40 per cent than on lower ones, due to an accumulative error because of titrating too rapidly.

For titrating the volume of the solution should always be the same. This is important, as well as the acidity and the amount of salts in solution. Use the same size drop, both of the indicator and the solution to be titrated, retaining the same conditions of spotting on the ore as were used on the standard.

There is one criticism I should like to make of the scheme given by Low,⁶ and that is in regard to standardizing. Low does not allow for the same amount of salts in solution in the standard as for the ore, and consequently, on 40 c.c., the standard runs 0.7 c.c. higher than if it was run through like the ore, thus making the determination of zinc 0.7 per cent too low in this particular case.

The standard solution contains 21.54 grams potassium ferrocyanide per liter, and 1 c.c. equals 0.005 gram of zinc or 1 c.c. equals 1 per cent on a 0.5-gram weighing.

The equation for the precipitation in an acid solution is evidently different from that in an alkaline solution, for the latter standard solution requires 16.25 grams potassium ferrocyanide per liter. The reason being that in an acid solution the precipitation is a potassium zinc ferrocyanide and in the latter a normal zinc ferrocyanide.

The method adopted by the American Chemical Society is as accurate as the one described, but not so simple or convenient in the manipulation. In the alkaline titration analysts have experienced trouble in getting a definite end point on the standard which holds good for the subsequent titration of the ore analyses. One scheme described even going so far as to insist on a standard being run with each set of twelve determinations, since the end point varied with the eight. Using Low's method there is no such trouble with the end point if a 5 per cent uranium nitrate solution is used, kept in an amber-colored glass bottle.

In the use of a method for determining zinc in an acid solution without the addition of hydrogen sulphide

water before titration, the chlorine apt to be produced gives high results.

Of the metals that interfere, manganese has been accounted for; copper is precipitated by the hydrogen sulphide water. Small amounts of cadmium are not precipitated by the latter. On a standard made up of 200 grams zinc and 0.015 gram cadmium sulphide, the result was 0.22 c.c. too high, equivalent to titrating an ore running 40 per cent zinc and about 2 per cent cadmium. Cobalt and nickel interfere, but are not found in the ordinary zinc ores of commerce. Acknowledgement is due Mr. J. W. Richards of Denver for many helpful suggestions.

Hydro-Electric Power and Electrochemistry and Electrometallurgy in France

By C. O. Mailloux, E. E., D. Sc.

(Member of the American Industrial Commission to France).

(This article contains the notes which were prepared by Dr. Mailloux to furnish information for the editors of the Report of the American Industrial Commission to France. A brief abstract of the first portion only, relative to hydroelectric power, was published in the Report. The second portion, relating to Electrochemistry and Electrometallurgy, has not yet appeared in print. The present installment contains the complete text of the first portion, and the complete text of the second portion will appear in a subsequent issue.—Editor.)

There is abundant evidence that the importance and value of hydro-electric power (the power generated by water and transmitted to and distributed at distant points by electricity) are thoroughly understood and appreciated in France. There is, indeed, no country in the world today where steps have been taken for such a comprehensive and exhaustive study of all the water powers available in the various parts of the country. This makes a somewhat detailed reference to the subject of considerable interest.

The art of utilizing water power and of transmitting energy to long distances by electricity is one in which France was a pioneer and a leader, and in whose development she has taken and is still taking an important part.

On the one hand, the possibility of obtaining power from the energy available in the water of mountain streams is of great interest to a country which, like France, produces only a portion of the fuel it consumes, and has to supplement its own production by importing large quantities of coal from other countries. Before the war the annual coal consumption in France was, in round numbers, 60,000,000 tons, of which amount about 40,000,000 tons were obtained from French coal mines, leaving a shortage of about 20,000,000 tons to be made up by importation from other countries.

On the other hand, there are numerous places where water power can be developed in considerable amounts in the mountainous regions of France, in the Northern and Southern French Alps, in the Vosges and Jura Mountains, and in the Pyrenees. The aggregate of this power is estimated at from 6,000,000 to 10,000,000 hp.

It is estimated, from statistics in regard to steam power in France, that about 75 per cent of the total coal consumed, or about 45,000,000 tons, is used for producing steam for generating mechanical power, aggregating about 12,000,000 hp. This corresponds to about 3,750,000 tons of coal per year for each million hp. of steam power capacity, so that the full development and utilization of 6,000,000 hp. of water power would, theoretically, more than make up for the entire coal shortage in the whole country.

The American Industrial Commission to France had the privilege of visiting the very interesting region where water power abounds—the so-called "white coal region" ("région de la houille blanche")—in the eastern

part of France, on the western slopes and watersheds of the Alps, and the Jura Mountains, where French scientists and engineers found both the incentive and the opportunity for the wonderful pioneer work done by them in hydro-electric power development and power transmission.

Evolution of Water Power. Before 1827 the only forms of water motor in general use in the world were the old-fashioned "waterwheels," now of historic or pictorial interest only, and seldom to be seen elsewhere than at some old-time grist-mill or in some picture of by-gone periods. These waterwheels were of small power capacity, in spite of their large size; they were not at all suited for the development of power in great amount from large and high water falls. There was a limit not only to the diameter that could be given to them, to adapt them to falls of greater height, but also to the length that could be given them, to adapt them to an increased volume of water from large streams. An idea of the inherent limitations thus imposed on the power capacity attainable with waterwheels of that now obsolete kind may be obtained from the best examples of such wheels, such as from the four remarkable breastwheels, each 50 ft. in diameter, said to be the largest in the world, erected at Catrine in Ayrshire, Scotland, by Sir W. Fairbairn in 1825. These monster wheels, a monument to the boldness of their designer, are still working; but as the capacity of each is only 125 hp., there is no likelihood of their serving as models for modern water motors. More than 1000 times that power capacity can now easily be put into the same space with a modern water motor.

The efforts made to devise a water motor more satisfactory than the old-fashioned waterwheel date from the year 1827, when a prize was offered, in France, by the Société d'Encouragement for an improved water motor. The modern type of water motor known as the "turbine" owes both its origin and its name to that offer. The prize was awarded to Fourneyron for his celebrated water motor, the first hydraulic "turbine." The wonderful perfection of this invention is sufficiently shown by the fact that the Fourneyron turbine is still being made extensively today, with but little modification in design. Moreover, Fourneyron had made such important contributions to the problem of securing proper speed regulation and high efficiency at varying loads and with varying amounts of available water that most of his methods and expedients for attaining these objects are still utilized in many cases.

Fourneyron's invention led to a rapid development in water motors of the turbine type, as the result of which it became possible to produce water motors of greatly increased power capacity, occupying much less space, and, especially, to use such motors for developing power from water falls of much greater heights and volumes than had been hitherto possible. The development of turbines suitable for producing large amounts of power, especially from high waterfalls, however, was slow. The reason is that for more than 50 years after the advent of the turbine there was little, if any, demand for such turbines. During all that time the only method of power transmission known to the world was that of mechanical transmission by means of shafting and belting, to very limited distances, and in limited amounts. Under such circumstances it was necessary either that the power should be developed very near the works where it was utilized, or else that the works should be located very near the place where the power was to be developed. In most cases turbines of large power and suitable for high heads were not necessary. It was more practical to use a greater number of smaller turbines. In the majority of cases no attempt was made to utilize either the full flow or the full head of the

stream. The result was that usually a great portion, often the greater portion, of the available power was not utilized.

As is well known, it was only after the advent of electric power transmission that there arose a demand for large prime movers for both water and steam power. Even as late as 1875 a hydraulic turbine or a steam engine of 300 or 400 hp. was considered a very large power unit. It is noteworthy that one of the "world wonders" at the Centennial Exposition in Philadelphia in 1876 was a pumping engine of 1000 hp., designed by Corliss, the great American engine builder. At that time this was considered, even by engineers, a unit too large to be practical. Even in spite of the advent of the direct-coupled engine-driven dynamo, which made a demand for larger steam engines, the largest unit at the Chicago Exposition in 1893, or seventeen years later, was barely 1000 hp. At the present time hydraulic turbines of 20,000 hp. and steam turbines of 75,000 hp. are no longer considered marvellous.

The highest development and the most important applications of hydro-electric power generation and transmission have resulted from progress in two important respects, namely, increase in the height or head of waterfall utilized for producing power, and increase in the electrical pressure or voltage utilized on the electrical transmission line. It is worthy of note here that these two features were first suggested and tried in France, in the very region visited by the commission.

High Head Hydraulic Turbine. Efforts to develop the hydraulic turbine in order to adapt it to very high heads were made by the original inventor himself, Fourneyron, as early as 1840, and again, later, in 1850, by another prominent French hydraulic engineer, Gérard, the inventor of the turbine of that name. The highest falls to which these men attempted to adapt turbines are said to have been of "over 100 meters" (328 ft.). The practical results do not appear, however, to have been entirely satisfactory. It was recognized that the hydraulic turbine would need to depart considerably from the standard types of Fourneyron and Gérard, in order to meet the requirements for high heads. The "reaction" type of turbine had been highly developed; but the "impulse" type needed further development. This was also realized in America, especially in mining work, where it is desirable to utilize streams of small flow and of high heads as sources of power. Attempts to solve the problem of obtaining power from waterfalls of high heads were made in America in the mining districts in California, beginning about 1860, which resulted in the construction of primitive "impulse wheels," known as "hurdy-gurdy wheels," carrying vanes against which jets of water were directed. The evolution of this "hurdy-gurdy" water motor led, in time, to the invention of the Pelton wheel. Some of these "hurdy-gurdies" were used with heads as high as 2100 ft. (640 meters). No attempt seems to have been made, however, to produce large power units, the largest sizes used being of only 100 to 125 hp.

A most interesting contribution to the evolution of the turbine was the invention, in 1867, of a new, highly practical and efficient form of "impulse turbine" by M. Aristide Bergès, a French engineer, proprietor of a large factory devoted to the manufacture of paper and woodpulp, located at Lancey (Department of Isère) near Grenoble.

M. Bergès in 1867 attacked the problem of utilizing the power obtainable from a nearby waterfall of 200 meters (656 ft.) as a source of mechanical power for his woodpulp works. His experiments and tests led him to design and construct a turbine of entirely new and very original type, which was put in permanent opera-

tion, giving satisfactory service, in 1869. This turbine, which is now preserved in a museum at Lancey, furnished power for grinding wood to make woodpulp fibre. It utilized the full head of the fall (200 meters, or 656 ft.). In 1873, after this turbine had been giving satisfactory results for four years, M. Bergès installed a second turbine, designed to utilize the water from a fall of 500 meters (1640 ft.). This turbine was remarkable, not only for the high head under which it could operate, but for the great power that it could develop (800 hp.), which entitles it, perhaps, to rank among the largest hydraulic turbines of that period. It was moreover remarkable, in fact epoch making in still one more respect, namely, that, as a hydraulic turbine of the "impulse" type, its design, construction and operation embodied substantially the same principles as appeared from twenty to twenty-five years later in the steam turbine of the "impulse" type; so that a person skilled in the art of designing steam prime movers, and properly informed in regard to the difference in physical properties and characteristics of the two "fluids" used, namely, water and steam, should have been able to evolve a satisfactory type and form of steam turbine from the Bergès hydraulic turbine. In the next few years other turbines were installed at the paper works, until the stream utilized, a small mountain brook, coming down from the glacier, which originally supplied only a nominal amount of power (not over 50 hp.), was supplying 2000 hp. to the works, besides furnishing power for generating electric current used for lighting in the surrounding villages. M. Bergès estimated, at the time, that the power made available by his efforts (about 3000 hp.) could be practically trebled by developing power higher up on the stream, so as to utilize the entire head. This more complete development of the stream is now in process of being carried out; so that M. Bergès's dreams of power development in Lancey and vicinity are coming true. At the 1889 exposition in Paris, M. Bergès exhibited one of the early turbines made by him, and he announced the fact that he was at that time designing a turbine equipment for developing power from a fall of 1718 meters (5635 ft.). This is perhaps the highest head that has been proposed for utilization by means of any form of water motor. A "tour de force" of this character was not an impossibility with the Bergès type of "impulse" turbine.

The American Commission visited the Bergès Works at Lancey by invitation, and saw several Bergès turbines in operation, including one installed over 40 years ago, which was still doing satisfactory service.

High-Voltage Electric Transmission. It happened that the vicinity of Grenoble was the scene of the first scientifically conducted tests of long-distance electric power-transmission. Those tests, which were made at different periods between 1880 and 1883, were conducted by an eminent French physicist and engineer, M. Marcel Deprez, for a syndicate of French capitalists. Their purpose was to determine, by practical trial, under diversified conditions, the amount of power which could be transmitted, the losses of transmission, the limitations as to distance and commercial feasibility, and, incidentally, to find ways of improving the apparatus used and the results obtained. The transmission line used extended from Grenoble to Vizille, a distance of about 20 kilometers. By making loops and detours in the line the transmission-distance could be increased to 50 kilometers or more.

These tests were epoch-making in many respects, but their greatest value was in demonstrating the importance of high voltage as a factor of economy and of commercial success in electric power-transmission. They pointed out the direction in which improvements

in methods and in apparatus must be sought in order to make success possible.

Distribution-System. While economy of transmission dictated the use of the highest possible voltage on the transmission-lines, the conditions attending the distribution of electric power at the receiving end of the transmission-line, and the necessity of avoiding all danger of harm to persons and property, introduced new problems, calling for means of reducing the voltage of the electric current "distributed" to the consumers. This was furnished by the development of the "transformer" during the last decade of the nineteenth century. This period marks the beginning of the rapid development of hydro-electric power in all parts of the world.

"White Coal." The term "houille blanche," meaning literally "white coal," for designating the power obtainable from the melting ice and snows of glaciers, is said to have originated with Cavour, the Italian statesman, but it was introduced and made popular in France by M. Bergès, the inventor of the high-head hydraulic turbine. He originally employed this term to designate all streams which are fed and regulated by glaciers, because the solidified water in the form of ice and snow in this glacier represents stored energy available for power, similar to the stored energy contained in ordinary ("black") coal. The energy available in streams not fed by glaciers was termed "green" coal ("houille verte"), because the energy comes from water stored in green vegetation. The expression "white coal" has, however, gradually enlarged its meaning, and it now means the energy of any waterfall that is available for developing water-power; therefore it now practically includes "green" as well as "white" coal, although the term "green coal" is still occasionally used.

"White Coal" Congresses. In September, 1902, a "white coal" or water-power congress was held at Grenoble, which was a great success. From statistics presented at that congress it appeared that the water-power already developed at that time, in France, aggregated about 200,000 hp. With a view to stimulating the development of water-power in all parts of France a resolution was adopted, requesting the Government to take steps to make a survey of the available water-power of France. In 1903 the Government took action by creating a commission for large water-powers, which was entrusted with the work of estimating the hydraulic resources of France. This commission has already studied a certain number of the basins in the Alps and in the Pyrenees, from the geographical, meteorological and hydrographic points of view. The results of these researches are published regularly. Six volumes have already appeared for the Alps and two for the Pyrenees. The commission has also published some very useful maps, giving information and data regarding the hydro-electric plants in the region of the Alps. One of these maps gives the locations of electric generating plants and the transmission and distribution systems up to 1912; another map, just issued (1916), gives the fullest and most recent information about the location and capacity of the principal water-powers and the work for which the power is used in the region of the Alps. (See map, page 266).

A second water-power congress, organized by an association of water-power owners, was to have been held at Lyon in September, 1914. It was, of course, postponed. It will likely be held soon after the war is over. The rapid development of water-power in France will doubtless make these congresses recur at shorter intervals in the future.

Water-Power Association. As in the case of all large industries in France, the water-power industry has its

interests looked after by a "get-together" organization, having a very comprehensive name, which includes all concerns interested in water-power, electrometallurgy, electrochemistry and "all the industries related thereto." The association is really composed of three distinct groups of industries, each of which has its council or board of directors; the first group, composed of concerns engaged in "electric power transmission and distribution," contains 54 member-companies; the second group, composed of concerns engaged in "electrometallurgy and electrochemistry," contains 24 member-companies; the third group, composed of "sundry and miscellaneous concerns," contains 30 member-companies. There is a general council, of not less than 12 nor more than 35 members, elected at the annual meeting from representatives of all three groups of member-companies. Continuity of policy in the council is secured by electing the members of the council for three years and changing only one-third of the total number each year. The council members elected from each group of member-companies also form, by themselves, a corresponding "section" of the council. Each of the three sections of the council must meet at least six times each year to consider matters of special interest or importance to that section. Its decisions and resolutions are subject to approval and review by the general council. The statutes (by-laws) of the association are similar to those of other French industrial associations or syndicates. They are a model of their kind. A practical means of securing co-operation and exchange of information and ideas between this and other similar industrial associations is to have the same person serve them all in the capacity of general secretary. His office is the information bureau for all the associations and their various sections, and he is the connecting link between them all. They all have their headquarters and hold all their meetings at the same place. Their co-ordination is remarkably complete and perfect, and they can co-operate for accomplishing a common object, on occasion, in a most prompt and efficient manner.

Available Water-Power. The work done by the Water-Power Commission, since it was organized in May, 1903, enables a fairly close estimate to be made of the water-power available in the region of the Alps, but it is still difficult to make any estimate of the water-power available in the rest of France. An official estimate made under the direction of the Water-Power Commission five or six years ago gives the following approximate figures:

	Low Water Flow, H.P.	Average Water Flow, H.P.
Northern Alps (Haute Savoie, Savoie Isere, Hautes Alpes)	1,000,000	2,000,000
Southern Alps	1,300,000	2,600,000
Central Alps, Vosges and Jura Mountains	900,000	1,800,000
Pyrenees and elsewhere	1,400,000	2,800,000
Total	4,600,000	9,200,000
Another, more conservative, estimate gives an aggregate of 4,500,000 hp. for low water, and 6,000,000 hp. for mean water.		

Capacity Developed. The official annual (1914-1916) report of the French Water-Power Association, already mentioned, states that the aggregate power-capacity of all the water-powers owned or exploited by the various power companies belonging to that association is 660,000 hp.. Of this total, 412,000 hp. represents power transmitted and distributed for general lighting and power purposes in cities, towns and villages; the rest (248,000 hp.) is power consumed by electrometallurgical and electrochemical industries. The distribution-systems owned by the power companies belonging to the association constitute a network of 16,200 kilometers (10,066 miles), of which 13,400 kilometers (8325 miles) are overhead lines and the rest (2800 kilometers, or 1740 miles) are underground lines. These distribution-

systems serve to supply electric current for light and power to communities aggregating between four and a half and five millions of inhabitants.

The capital investment represented by all these plants exceeds 600,000,000 francs.

The greater number of these plants are located in the region of the Alps. As there are also many water-powers, both in the Alps and elsewhere, which are operated by companies and individuals who are not members of the Water-Power Association, the preceding figures for power developed are presumably too low for the whole of France. According to statistics prepared by the French Water-Power Commission, the total installed power-capacity in the eastern regions alone exceeds the total given above. The official figures, for Dec. 31, 1915, as reported by the commission to the Government, show the following results:

Hydraulic Power-Capacity Installed in the Region of the Alps

	H.P.	% of Total
Power used for light and power.....	291,000	39.4
Power used for electrometallurgical works.....	255,000	34.6
Power used for electrochemical works.....	147,000	19.9
Power used for electric traction.....	16,000	2.2
Power used for paper mills, saw mills, etc.....	23,000	3.1
Power used for various industries (lime and cement works, spinning, etc.).....	6,000	0.8
Total.....	738,000	100.0

These figures agree substantially with those given on the map issued, as already stated, in 1916, by the Water-Power Commission.

Of the above total, the basin of the Isère River furnishes 427,000 hp. and the basin of the Durance River furnishes 112,000 hp., the rest (199,000 hp.) being furnished by the basins of the Rhone and other streams.

The 1916 map gives the following additional information for the same region:

Power-plants under construction or for which contracts have been made.....	100,000 hp.
Water-powers whose development is contemplated or proposed.....	700,000 hp.

The American commission saw evidence of great activity in further developments of water-power, many of them of considerable magnitude and importance, at various points in the "white coal" district. The members were given the opportunity to see several power-sites where the construction of dams, intake and discharge canals, power-station buildings, transmission-lines, etc., were under construction.

In addition to the projects now in process of realization there are many more that are in contemplation for the future. The pioneer work of Bergès has borne fruit in the development of the impulse turbine for high heads, and of large power-capacity. There is no longer any hesitation to utilize falls of 1000 to 2000 meters (3280 to 6560 ft.) in height, in one station, instead of doing it in a number of steps or stages, with a dam and a power-station at each stage, in order to reduce the working head and pressure at each stage, and turbines of 10,000 to 20,000 hp. are coming into use. The highest fall developed in France up to the present is at Orlu on the Argeège River, where the fall is 940 meters (2983 ft.).

The two most important water-power projects are those known as the "Durance" and the "Upper Rhone" projects.

Durance Project. This project is aimed at the utilization of the water of the Durance River in the south-eastern part of France, at a point about 200 kilometers (124 miles) from Marseilles. The project is in the hands of a syndicate known as the "Société pour la régularisation de la Durance," composed largely of people who are already interested in many of the large water-power companies owning plants in the region of

the Alps. The head of the syndicate is the managing director of the companies already owning and operating the largest water-powers in that region, including one on the Upper Durance of 30,000 hp. and one in the Mediterranean Coast region of 32,000 hp., and he is a director in seven other companies operating smaller plants, the aggregate of all the plants being a power-capacity of over 110,000 hp., representing a capital investment of over 140,000,000 francs. From this it will be seen that the Durance project is in the hands of competent, experienced persons. The dam will be located at Serre-Ponçon. It will have a height of 85 meters (279 ft.) above mean low water, and of 127 meters (417 ft.) above the rock-foundation. The storage-reservoir produced by this dam will hold 600,000,000 cubic meters of water. This will enable the flow of water below the dam to be regulated so as to secure minimum steady flow at the following rates:

During six autumn and winter months, 50 cubic meters (13,210 gal. per second).

During three spring months, 65 cubic meters (17,173 gal. per second).

During three summer months, 75 cubic meters (19,815 gal. per second).

The power available with these quantities of water will range from about 70,000 hp. in summer down to somewhat less than 50,000 hp. in winter. The power-station, which will be installed near the dam, will comprise eight units of 10,000 hp. each. The greater portion of this power will be utilized for electrochemical products, especially for making cyanamide and other nitrogenous substances, and also for electrometallurgy. The estimated cost of this power-development is 36,000,000 francs.

Upper Rhone Project. The Rhone is the outlet of Lake Lemman (sometimes called the "Lake of Geneva"), which constitutes an enormous storage reservoir for that river. In the Swiss portion of the Upper Rhone, extending from Geneva to the French frontier, a distance of about 18 kilometers (11 miles), the city of Geneva itself has been active in developing water-power. It began as far back as 1713, when the hydraulic power of the Rhone was utilized to furnish power for pumping water for the city of Geneva. The old water-pumping station, after undergoing innumerable repairs, extensions and improvements, during a period of nearly two centuries, was finally replaced by a new, modern water-pumping station, begun in 1883, and finished in 1887, which was, and remains, the model of its kind. The world-wide interest excited by this plant was largely responsible for the appointment of its designer, the late M. Turettini, later Mayor and Commissioner of Public Works of the City of Geneva, as one of the members of the commission of eminent scientists and engineers that outlined the plans for water-power development at Niagara Falls.

The dam serving for this pumping-plant also serves for the very important purpose of regulating the flow of water from Lake Lemman into the Rhone, so as to keep the level of that lake within certain limits, the extreme variation allowed at any time between highest and lowest levels being only 60 centimeters (about 2 ft.). The hydraulic power developed at that station is about 6000 hp. Another interesting feature of this plant, which deserves mention here, is that the water pumped at this station and sent into Geneva was used considerably, and is still used to some extent, in Geneva for driving water-motors; so that, in effect, the problems of power-transmission and distribution were solved here in an original manner, and with some success, *hydraulically*, several years before the problem was solved *electrically*.

Between 1893 and 1896 the city of Geneva built another larger water-power plant further down stream, below the point where the Arve River empties into the Rhone. This station is a hydro-electric station; the whole of the power developed (about 12,000 hp.) is used for driving electric generators; none of it is used for pumping.

A third station, under construction, still further down stream, will develop about 18,000 hp., and, eventually, there will be a fourth station of about 8000 hp. From what precedes, it is seen that the power already developed and available for future development, in the Swiss portion of the Rhone, aggregates over 50,000 hp.

On the French side of the frontier, the Rhone runs through deep gorges and over many falls, which, in a distance of 23 kilometers (14.3 miles) from the frontier, make an aggregate drop of from 67 to 69 meters (220 to 226 ft.), according to the time of the year. This drop, if produced at one point by a dam, would be considerably higher than Niagara Falls, which is less than 200 ft. The volume of water, which is already increased by the water emptied into the Rhone by the Arve, near Geneva, is still further increased by the water of a second stream, the Valserine, which empties into the Rhone at a point about 15 kilometers (9.3 miles) below the frontier.

The mean flow of the stream, at Genissiat, a place situated 23 kilometers (14.3 miles) from the Swiss frontier, is about 300 cubic meters (79,260 gal.) per second. The utilization of this volume, with the full drop, taken at an average of 68 meters (223 ft.), would represent a useful power of over 200,000 hp. It would seem, therefore, that this portion of the Rhone presents the opportunity for one of the largest water-power developments in France.

The possibilities of the French Upper Rhone as a source of water-power attracted attention as early as 1871, or long before electric power-transmission was even dreamed of. At that date, an English company obtained authority to build a water-power plant on the Rhone at Bellegarde, about 14 kilometers (8.7 miles), from the Swiss frontier, with the right to utilize an average fall or drop of about 12 meters (39.4 ft.), and a volume of water of 60 cubic meters (15,852 gal.) per second, which was estimated to represent a useful power-capacity of about 6400 hp. The originators of the project intended to transmit power *mechanically*, by means of long belts made of rope or cable, running over large sheaves, as had been done to some extent in England. Those "rope-drive" transmissions of mechanical power were to serve for distributing the power produced at the power-station to various factories and works located in the immediate vicinity of the station. This scheme, which was without doubt the largest and boldest scheme of power-transmission and distribution of that period, was a financial failure, because there was not enough demand for the power thus made available to make the enterprise pay. The power-plant eventually passed into the hands of another company, and it lay practically idle until interest in it was revived in the late nineties, after the problem of power-transmission had been solved by the aid of electricity.

Various projects have been proposed in recent years for the development of water-power on the French Upper Rhone. One project is based upon the plan of utilizing a fall or drop of about 20 meters (65.6 ft.), which would mean a power-capacity of 20,000 to 40,000 hp. Another project aims at the utilization of a fall of 21 meters (68.9 ft.), which would give a somewhat increased power-capacity. Reference will be made, in some detail, to a third plan, which aims to utilize, by means of a single dam and at a single power-station, the whole of the energy obtainable from the stream be-

tween the Swiss frontier and the village of Genissiat, situated 23 kilometers downstream. This project was worked out by three distinguished French engineers, Messrs. Blondel, Harlé and Mähl, in 1905. As their plans contemplated the transmission of energy by electricity from this plant to Paris, a distance of 450 kilometers (279 miles), a "White Coal Commission," composed of 31 members, including the most distinguished civil, electrical and mechanical engineers in France, and also including many able scientists, economists and men of affairs, was appointed by the Prefect of the Seine to make a full inquiry into and to report upon the feasibility and merits of the project. This commission rendered a favorable report in 1908.

In 1909 a syndicate was formed to make a complete detailed study of the technical, engineering and financial features, and to work out the more important details of the project. The work of this syndicate, which included the thorough exploration of the region, by borings, soundings, etc., was completed in the early part of 1912. The plans for the project are very complete, and they show that the work of their preparation received the most exhaustive and thoughtful study, and that it was done with great care and thoroughness, with the desire to work out the most minute details and to anticipate all difficulties and meet all objections. The two principal difficulties incidental to this proposed water-power development are: First, the sudden freshets, occasionally of flood-like character, due not to the water from Lake Lemane, whose flow is regulated and controlled by the city of Geneva at the pumping station, as already stated, but to the waters of the two tributaries, the Arve and the Valserine, which discharge into the Rhone above the proposed dam-site; second, the alluvial deposits resulting from matter eroded and then deposited by the stream at places where the current is slow. The engineers have anticipated these difficulties and have made adequate provision against them.

A few figures taken from the reports of the authors of the project will suffice to give a general idea of the project. The plans contemplate a dam at Genissiat of stone and armored concrete of 76 meters (249.3 ft.) in height, which will dam up the water to a head of 69 meters (226 ft.) in the low water season and of 64 to 65 meters (210 to 213.3 ft.) in season of high water. This will raise the stream level above the dam high enough to fill the gorges of the Rhone as far up stream as the Swiss frontier, thereby making a lake of 23 kilometers (14.3 miles) in length, which will constitute a large storage reservoir for the power-station, with a capacity such that, by allowing the level to fall 4 meters (13.1 ft.) a water reserve flow of 15,000,000 cubic meters (nearly 4,000,000,000 gal.) can be obtained, which, with the lowest head (64 meters) would represent a supply of energy of not far from 1,000,000 hp.-hours. The average power available will range from a minimum of 80,000 hp., in the low-water season, to 320,000 hp. in the high-water season; and even in the low-water season the storage reservoir will enable the plant to carry a "peak-load" of 160,000 hp. It is interesting to note that while the dam will be of lesser height than that required for the Durance project, the total power developed will be very much greater.

It is proposed to transmit electrically to Paris a portion of the energy obtainable from this plant, using three-phase current of 25 periods, at a pressure of 120,000 to 140,000 volts. The voltage will be reduced, near Paris, to a suitable voltage (about 15,000 volts) for distribution to large power consumers; and it is also proposed to use apparatus for changing the frequency and otherwise adapting the current for lighting and other requirements. A considerable portion, perhaps the greater portion, of the power developed would be

distributed at various places much nearer the power-station than Paris. The engineers assert that, since the plant will find a market for its power at all points along the whole way to Paris, there will be no difficulty in disposing of the entire power output of the plant at all times. The total cost of this development will range between 130 and 160 million frs., depending upon the extent of the transmission and distribution system.

The very magnitude of this project made it seem somewhat utopian in a country like France as it was before the war, whereas it would not have seemed so stupendous even for France, in the eyes of American engineers and capitalists, who are more accustomed to large power projects. The enormous activities in mechanical industry which have resulted from the war, and the consequent great demand for power, so sudden and so hard to meet, which occurred, have unquestionably caused a great change in opinion and in attitude, in France, on the subject of power-supply, especially since the price of coal has risen to such extraordinary figures. The project would presumably look far more attractive to-day to financiers than it did five years ago; and it is possible that some of them now regret that they did not then show more interest in it.

The estimated annual output of useful energy from this plant is 1,300,000,000 kw.-hr. To produce the same energy by steam power 1,800,000 tons of coal would be required. Allowing 25 francs per ton, the present minimum price for domestic French coal, the value of the yearly output of the plant would be 45,000,000 francs. This would be equal to 15 per cent of 300,000,000 francs of capital investment. We may say, therefore, that this is what the plant would have been worth to-day. It would not have cost anywhere near that sum. Of course, if a part of the coal which the plant would have eliminated is taken at the cost of imported coal, then the financial results are even more impressive.

There is very little reason to doubt that this important water-power development will be made some day, perhaps in the near future.

Pyrenees and Elsewhere.—Although a considerable amount of water-power has already been developed in this region, there is still much to be done there. The lack of market for power has been the principal drawback. It may prove possible there, as it has in the "white coal" region of eastern France, to develop electrochemical and electrometallurgical industries which would utilize a great portion of this power. This is in the minds of many people in France, and some initiative in that direction may result before long. Now that it has been demonstrated in America that very high transmission-voltages (100,000 to 140,000 volts) are practicable, the radius of territory which can be reached and served by long-distance electric power is so much increased that even places like Bordeaux come within the range of the power obtainable from the Pyrenees. A great increase may be expected in the amount of water-power developed in the region of the Pyrenees in the next few years.

A certain amount of hydroelectric power is already obtained from the Dordogne River, at Tuiliere, near the point where that river empties into the Garonne, some 40 or 50 miles east of Bordeaux. The "Southwest Power Company" which operates this plant—from which power is sent as far as Bordeaux itself—has in contemplation other hydroelectric developments farther upstream on the Dordogne which, it is expected, will bring the total power from that river up to at least 50,000 hp. There is therefore, a good prospect that Bordeaux will have, in time, a good supply of cheap electric power.

The streams in the hills of Normandy and Brittany

if properly developed under modern methods can be made to yield power in small amounts, which, however, would be only of local interest and importance.

Outlook and Prospects.—The water-power industry is one which is generally regarded in France as having earned the right to be encouraged and fostered by both the public and the government. The plans in process of execution and in process of preparation indicate that the aggregate power developed in France will reach 1,500,000 hp. in the next two or three years. This will be still less than one-third of the estimated total power available during the periods of lowest water; yet it will be the equivalent of five or six millions of tons of coal per year that would otherwise have to be provided to do the same work, and which would become an item of the coal shortage that has to be made up by importing coal from other countries.

Irrigation.—In America, water power developments are frequently identified with irrigation projects; indeed, they are, sometimes, merely incidental to such projects. In France, where the soil is not arid to any extent, the utilization of water for irrigation purposes is of secondary importance, in comparison with the development of power. Nevertheless, in certain regions, notably in the southern districts, in Provence, irrigation is capable of producing great results. Its possibilities are kept in view and the uses made of it will increase greatly in the near future. There is interesting work to be done there by the irrigation engineer in adopting the plans and methods which have proved successful in the arid regions of the United States.

Growth of Electric Service.—The existence of nearby and cheap sources of electric current-supply in the "white coal" region has made itself evident in facilitating and increasing the use of electricity for lighting and power in the towns and villages of the region itself, and also of neighboring regions. In many places the low cost of electric current has made it possible for even the farmer to utilize it for lighting and power, to lighten his tasks and increase his comforts. Even stables have been lighted by electricity; and the cattle has had better care, in consequence. It is stated that the supply of electric light in the farming communities has led to the increase of profitable reading and study on the part of the inhabitants, producing a cultural effect of much value, and that it has also had a favorable influence on the development of agriculture by facilitating the desire and efforts of the farmer to add to his knowledge and to improve his situation.

The facility with which the power can be distributed to families and small workmen's associations has led to the establishment of small home factory plants, not only in the village communities but even in cities like Lyons and St. Etienne and similar industrial sections, in this way giving a new impetus to home industry to counterbalance the concentration of many hands in large factory plants.

It is not in the small communities alone that there has been a great increase in the use of electricity. Indeed, one of the most striking examples of such increase is to be found in the city of Lyons, the third largest and the most important industrial city in France. The manner in which the consumption of electrical energy has grown in that city, as traced by the statistics, is very remarkable, and also very instructive, as showing how greatly reduction in the cost and improvement in the quality of service may stimulate the consumption.

The total electrical energy consumption in kilowatt-hours, supplied by the electric plants of the Lyons Gas Company, has increased from 399,100 kw.-hr. in 1897 to 35,400,000 in 1915, or, at the end of eighteen years, it was over 90 times greater. Surprising as this growth

is, there is still greater surprise in finding that 88 per cent of it occurred in the last five years of that period. Up to 1910, the annual increase in number of patrons or in total consumption was low; and the curve of growth, obtained by plotting the yearly totals of customers or of consumption, flattened out in a way that would have led any statistician to believe that the maximum of electrical consumption had been practically reached and that this maximum would probably not exceed 4,000,000 kw.-hr. per year. In April, 1910, the company made an important reduction in rates, in anticipation of the completion of its new power station, then under construction, and which was put in operation in 1911. The effect of these measures on the number of customers and on the total consumption was apparent in the total consumption for 1910, which showed an increase equal to that noted during the four previous years; and it became marked in the totals for the year 1911, which showed an increase as great as that which had occurred in the thirteen years preceding. In 1912 and in 1913 the growth in consumption was still greater (from a total of 7,000,000 to 16,500,000 kw.-hr., or an increase of more than 100 per cent in these two years). At the end of 1913, the total consumption was, in round numbers, four times larger than it was at the end of 1910. At the end of 1915 the total consumption was over eight times that for 1910, and five times that for 1911.

Cost of Electrical Energy.—The rates which went into effect in Lyons in 1910 fixed the cost of current, per kilowatt-hour, at 60 centimes for domestic lighting, at 55 centimes for stores, offices and factories, at 50 centimes for hotels, cafés, restaurants, theaters, churches, schools, etc., and at 40 centimes for small power consumers. Discounts were to be allowed as follows:

Amount of Discount	Lighting Current	Small Power Current
2 per cent on bills of.....	100 frs.	25 frs.
5 per cent on bills of.....	250 frs.	100 frs.
10 per cent on bills of.....	500 frs.	500 frs.
15 per cent on bills of.....	1,000 frs.	1,000 frs.
20 per cent on bills of.....	1,500 frs.	1,500 frs.
25 per cent on bills of.....	2,000 frs.	2,000 frs.
30 per cent on bills of.....	2,500 frs.	2,500 frs.

There was also a "flat" rate, per annum, for incandescent lamps. This rate varied with the kind of lamp, its candle-power, and the number of hours per day that it was to burn. For large power-current consumers there were special rates, either by meter, or else "flat," by the year. The meter rates, in centimes per kilowatt-hour, ranged from 20 for motors of 1 hp., to 16.5 for motors of 10 hp., to 13.8 for motors of 20 hp., to 12.5 for motors of 30 hp., to 10.9 for motors of 40 hp., and to 9.5 for motors of 50 hp. For still larger motors, the rates were further reduced; the lowest rate for motors working during "off-the-peak" hours, such as at night, is 5 centimes per kilowatt-hour. These prices have had to be increased since the war, on account of the high cost of coal. There is, indeed, no special desire at the present time, to induce the consumers to increase their consumption, but rather a desire to have them do the opposite, because there is so much more power needed than usual for works producing war munitions and supplies.

In a large munition works, visited by the commission, in Lyons, where the electric motors installed aggregate about 6000 hp., the electrical energy supply required is derived from two different systems of distribution. The amounts of electrical energy consumed for lighting are metered separately from those consumed for power in both cases. The cost of lighting current is the same in both cases, 20 centimes per kilowatt-hour (equivalent to about 4 cents, before the war, and to less than 3 cents with present rates of exchange). The cost of the

power current is different in the two cases; in one case it is 6.5 centimes (about 1.3 cent) for night work, and 7.5 centimes (about 1.5 cent) for day work, or an average of 7 centimes; in the other case, the average cost is about 15 centimes (about 3 cents) per kilowatt-hour, or more than double the cost of current from the first system. The total number of employees in the works was between 11,000 and 12,000, working in two shifts per day of 24 hours. The bills for electric current averaged about 2500 francs per day. The cost of electrical energy for lighting and power is kept separately for each department of the works. In the department devoted to the manufacture of 75 mm. shells the cost of electrical energy for both lighting and power was stated to be about 12 centimes per shell.

In the city of St. Etienne the prices charged for electric energy for lighting and power cannot exceed certain maximum rates which are stipulated in the franchise granted by the city to the electrical company that supplies electric current in that city. For lighting current the maximum rates decrease with the number of hours of use per year, as follows:

For the first 1,000 hours.....	55 centimes per kw.-hr.
For the next 400 hours.....	50 centimes per kw.-hr.
For the next 400 hours.....	45 centimes per kw.-hr.
For the next 1,500 hours.....	40 centimes per kw.-hr.
For all other.....	30 centimes per kw.-hr.

The number of hours of use per year is obtained by dividing the total number of kilowatt-hours consumed during the year by the total capacity of lamps installed, measured in kilowatts.

The franchise also gives the maximum figures allowable for "flat-rate" lighting current.

For power, there is a "flat-rate" scale of charges per horsepower per year, and there are also two methods of charge for "metered" current, as follows:

(a) A rate which is constant, independently of the total amount consumed per year, and which is fixed at a maximum of 30 centimes per kilowatt-hour.

(b) A rate which is not constant, but which decreases with the size of motor and the total yearly current consumption, and also requires a certain yearly minimum payment per kilowatt to be made by the consumer independently of the total current consumption indicated by the meter.

The latter method of charge (b) is that known as the "fixed-plus-variable charge" method. The variation of cost (in centimes per kilowatt-hour) with the size of motor and with the number of hours of use per year are shown in the table following:

Capacity Installed, kw.	Minimum Fixed Annual Charge Per Kw. Installed	Centimes Per Kilowatt-Hour for			
		First 1,000 hrs.	Next 1,500 hrs.	Next 2,000 hrs.	All Above 4,500 hrs.
0 to 2.....	240 frs.	30	30	25	20
2 to 4.....	200 frs.	25	25	20	15
4 to 6.....	160 frs.	20	20	15	10
6 to 10.....	155 frs.	19	15	9	5
10 to 15.....	150 frs.	18	12	8	5
15 to 24.....	150 frs.	17	11.5	7.5	5
24 to 36.....	150 frs.	16	11	7	5
36 to 50.....	150 frs.	15	10	6.5	5
50 and over.....	145 frs.	14	9.5	6	5

In St. Etienne and vicinity there is much weaving and like textile work done on looms and apparatus located in the workers' homes, and the small motors installed for these and similar purposes aggregates over 3000 hp. It is very important to have a finely graded sliding-scale for power current, like the above scale.

It will be seen, from the table, that the minimum price for metered power current comes down to as low as 5 centimes (approximately 1 cent) per kilowatt-hour, same as at Lyons. This is a very low figure, which will be a revelation to most users of electric power in American cities. This low cost would not be possible in cases where "black" coal is the principal source of energy, instead of "white" coal.

This low cost of power current shows the great benefits which have been derived in a large region of France from the development of hydroelectric power in the "white coal" region. They constitute the best possible argument in favor of further and even increased activity in the development of hydroelectric power wherever it is available in France.

For the purpose of comparison with power costs in a region where "black coal" is the only source of power, we may take the cost of electric power at Bordeaux. The power used for operating the coal and ore-handling and conveying system at the Bordeaux docks costs 12 centimes per kilowatt-hour. This is to be regarded as a low figure for electric power current derived from a steam station, even allowing for the advantage which a seaport city has of being able to get its coal supply at lower cost than an inland city. Nevertheless, this very reasonable cost is still 2.4 times greater than the lowest cost of electric power at Lyon and at St. Etienne. This is a significant fact.

The author desires to give expression here to his profound gratitude and his sincere thanks to all persons who have, in one way or in another, contributed to the fund of information and data of various kinds which have been utilized in the preparation of this article. He considers that special acknowledgments are due to the following persons: To M. Robert Pinot of Paris, General Secretary of La Chambre Syndicate des Forces hydrauliques de l'Electrometallurgie de l'Electro-Chimie et des industries qui s'y rattachent (the French "Water Power Association"), for his great courtesy and kindness in giving so much personal attention to the requests made of him for data and information and for furnishing the same so liberally and generously, in the form of printed reports, maps, etc., supplemented by valuable personal notes and explanations; to M. Maurice Bergès of Lancy (Isère), for the complete information kindly furnished by him in reference to the valuable pioneer work done by his distinguished father, the late M. Aristide Bergès; to M. A. Blondel, Membre de l'Academie des Sciences, the distinguished scientist and engineer, for fully detailed information regarding the Génissiat project for the hydroelectric power development of the Upper Rhone; to M. d'A. Carafa, manager of the Gas Company at Lyons, and to the officers of the electrical company at St. Etienne for information given by them in regard to the character and cost of the electric lighting and power service in these places.

(A second article on electrochemistry and electrometallurgy in France will follow.)

Potassium Chlorate in Japan.—A very interesting phase in the manufacture of this product has developed since the starting of the war, in Japan. Previous to the war there was only one firm in Japan manufacturing this product. This was the Nihon Kagaku Kogyo Kabushik Kaisha, which produced 300 tons of chlorate per year. The consumption of potassium chlorate in Japan at that time was about 4000 tons per year and was imported from Germany and other European countries. Since then the number of manufacturing concerns has increased from one to at least eight, which have an annual output of over 3500 tons. At present this output exceeds the local demand and of late a considerable amount of potassium chlorate has been exported to China, Russia and the South Sea Islands. During the months of August and September the above mentioned eight firms exported a total amount of 534,268 pounds of chlorate. A peculiar phase of this industry is that the firms manufacturing this product must have the permission of the government before permitted to export.

A Bibliography of Alloys: Binary, Ternary and Quaternary Systems Whose Equilibria Have Been Investigated

By Clarence Estes

The study of alloys in a systematic way began in the latter part of the nineteenth century coincident with the introduction of the pyrometer and the microscopical examination of metals. The introduction of these instruments made it possible to go much deeper into the study of the equilibrium diagrams of alloys. Because of the many requirements for alloys with special properties, a complete systematic study of the equilibrium diagrams of alloys should include at least the following investigations of each member of the series: (1) thermal equilibrium, (2), thermal expansion, (3) thermal-electric force, (4) molecular volume, (5) density, (6) hardness, (7) tensile strength, (8) ductility, (9) electrical conductivity, (10) solution tension, (11) magnetic susceptibility, (12) separation and identification of compounds, (13) microscopical examination, (14)¹ x-ray examination, (15)² optical rotation of polarized light from polished surfaces, (16)³ photoelectric effect, and possibly others.

Various investigators have studied more or less completely practically all of the binary systems of the common metals and a great many of the rarer metals; also about sixty ternary systems, and several quaternary systems. Tammann⁴ has summed up in the form of a chart the various binary systems which have been investigated under his immediate supervision at the Göttinger Institut für Anorganische Chemie. Bornemann,⁵ Faust⁶ and others have given short summaries of the binary systems of alloys, but so far as the writer is aware there has not been published a paper listing all the binary, ternary and quaternary systems investigated, and including a bibliography of each system. It is owing to this fact that the writer has endeavored to show in a chart all the binary systems which have been published, and also to include a list of ternary and quaternary systems which have been abstracted and published in the Chemical Abstracts up to Jan. 1, 1917, and the more important investigations prior to the publication of the Chemical Abstracts.

The chart of the binary systems investigated is published on page 274 and is immediately followed by the list of references to each system investigated.

The list of references to ternary systems investigated begins on page 281, that of references to quaternary systems investigated on page 281.

In many cases it was very difficult to decide whether the data were sufficient to justify including a system in the chart or not. No doubt, in some cases, systems have been included which some readers may think should have been omitted, while, on the other hand, some systems may have been omitted which should have been included. However, the writer, if in doubt, has endeavored to include a system rather than omit it.

Accompanying the chart is a list of references for each system investigated. A number in a square on the chart indicates that that system has been investigated, and this number refers to a citation in the list of references. Letters under certain elements in the first row indicate that those elements have had their Allotropic modifications investigated, and these letters also refer to a citation in the list of references. The bibliography has been compiled mainly from the Chemical Abstracts, from Desch's Metallography, and from original articles.
